13   **Abstract**

14   Integrated Arable Farming Systems (IAFS), which involve a reduction in the use of off-farm inputs,

15   are attracting considerable research interest in the UK. The objectives of these systems experiments are

16   to compare their financial performance with that from conventional or current farming practices. To

17   date, this comparison has taken little account of any environmental benefits (or disbenefits) of the two

18   systems.   The objective of this paper is to review the assessment methodologies available for the

19   analysis of environmental impacts.   To illustrate the results of this exercise, the methodology and

20   environmental indicators chosen are then applied to data from one of the LINK - Integrated Farming

21   Systems experimental sites.   Data from the Pathhead site in Southern Scotland are used to evaluate the

22   use of invertebrates and nitrate loss as environmental indicators within IAFS.   The results suggest that

23   between 1992 and 1995 the biomass of earthworms fell by 28 kg per hectare on the integrated rotation

24   and rose by 31 kg per hectare on the conventional system. This led to environmental costs ranging

25   between £2.24 and £13.44 per hectare for the integrated system and gains of between £2.48 and £14.88

26   for the conventional system. In terms of nitrate, the integrated system had an estimated loss of £72.21

27   per hectare in comparison to £149.40 per hectare on the conventional system. Conclusions are drawn

28   about the advantages and disadvantages of this type of analytical framework.

29

---

1. Introduction

The impact of agricultural systems on the environment is of increasing concern generally, and there is a growing body of research into the quantification of environmental benefits and disbenefits resulting from agriculture and other rural industries. However, little work has concentrated on the valuation of environmental benefits and disbenefits at the farm level with few considering the trade-off between financial and environmental impacts.

The objective of this paper is to provide insights into possible approaches to both the valuation of environmental benefits and disbenefits at the farm level and the resultant trade-offs between financial and environmental impacts. This is achieved through the use of data from a case-study farm at Pathhead in Southern Scotland.

This farm is part of the LINK Integrated Farming Systems (IFS) Project (Ogilvy et al., 1994), a five-year rotational systems experiment which was established to compare conventional and integrated arable farming systems in six different agro-ecological zones around Great Britain. The main objective of the LINK-IFS experiment was to test the practical and financial feasibility of such systems whilst taking into account the level of inputs being used and their environmental impact. As a result, they were able to provide the financial and environmental data for use in this study, which starts with a brief review of the assessment methodologies and trade-off frameworks used in the analysis.

2. Environmental economic modelling

2.1. Overview

Analysis of the trade-off between financial returns from farming and its environmental impact is based on the use of combined environmental economic models, providing a framework that allows both conventional agricultural production and the production of externalities (Wossink et al., 1996). Farming systems can therefore be analysed from both financial and environmental viewpoints to evaluate trade-offs between the two criteria.

1   Early examples are provided by the materials balance framework of Ayres and Kneese (1969) and

2   input-output analysis developed by Leontief (1970). Both approaches successfully highlighted some

3   interactions between the economy and the environment offering convenient classifications for

4   environmental impacts at various stages of economic activity. More recent examples are from

5   environmental impact assessment (EIA) (Glasson et al., 1994). EIA deals with four key problem areas:

6   identification, prediction and measurement, interpretation, and communication.

7   Impact identification techniques (Bisset, 1983, 1988; Wathern, 1984) date from the 1970s and include

8   checklists (Dee et al., 1972), networks (Sorenson, 1971), and matrices (Leopold et al., 1971). They

9   provide a simple enumeration of the impacts of an action, concentrating on pollution and soil erosion

10   and, to a lesser extent, social impacts such as recreation and employment. Economic considerations are

11   virtually ignored and they tend to not give the probability, importance or magnitude of the likely

12   impacts of an activity.

13   Key concepts involved in the measurement of environmental impacts are scoring to standardise the

14   information for comparative purposes using qualitative or quantitative methods and weighting to reflect

15   the relative importance of different impacts. Possible approaches to measurement and valuation include

16   the construction of indices (e.g., Kelly et al., 1996), energy use analysis (e.g., Taylor et al., 1993) and

17   monetary valuation. Pearce et al. (1989a) argue that it is important to place monetary measures on

18   environmental gains and losses for capturing the intensity of preference and degree of concern for the

19   environment. Extensive literature exists on the economic valuation of the environment covering both

20   theory (e.g., Pearce et al., 1989b; Meister, 1990) and also practical applications (e.g., Dixon and

21   Sherman, 1990; James, 1994). Identification of impacts and their measurement or valuation are then

22   combined in the environmental economic models. Cost benefit analysis (CBA) and multi criteria

23   analysis (MCA) are the most common such approaches.

24   CBA applies monetary values to all costs and benefits resulting from an action to be undertaken

25   (Mishan, 1975). It is particularly useful in identifying and measuring the impacts of projects or policies

26   to provide a criterion to judge projects given the objectives set, whether economic, social or

27   environmental. However, there are problems in the identification, enumeration and putting monetary

28   values on intangibles. Value judgements also have to be made to evaluate impacts in the absence of

29   adequate market prices.

1   MCA is a set of procedures, based on mathematical programming, designed to help choose between

2   options (Romero and Rehman, 1987, 1989) particularly, for estimating the effects of alternative policy

3   measures on financial returns and the environment. The advantage of MCA is that it permits

4   simultaneous consideration of multiple decision criteria, unlike single objective linear programming

5   (LP), without the need to specify incommensurable criteria in a common metric of monetary values.

6   Alongside current interest in MCA is the considerable amount of work on environmental and natural

7   resource accounting (see Ahmad et al., 1989; Lutz, 1993; United Nations, 1993). Such accounting is a

8   comprehensive incorporation of the environmental impacts into the system of national accounts to allow

9   the assessment of the trade-offs between the benefits and disbenefits of production and consumption

10   activities. These approaches *provide a coherent picture of resource use and depletion or increase,*

11   *which can be linked to, or integrated with, the national accounts* (Bartelmus, 1989). Two examples are

12   the Norwegian system of resource accounting (Alfsen et al., 1987) and the French patrimony accounts

13   (Theys, 1989).

14

15   *2.2. Suitability for the analysis of Integrated Arable Farming Systems*

16   Considering the problem of evaluating environmental consequences from Integrated Arable Farming

17   Systems (IAFS) in relation to financial return, and in comparison with other farming systems, the most

18   appropriate approach has to incorporate an assessment of both these factors. The above methods

19   achieve this objective, some providing useful insights into the valuation of environmental impacts,

20   others providing frameworks in which trade-offs between environmental impacts and the financial

21   return of the farming systems can be easily identified. Of particular interest is the use of environmental

22   and natural resource accounting as it provides an assessment framework already well-established and

23   understood. Furthermore, the financial analysis of farming systems, already uses this approach and the

24   expansion of these accounts to incorporate environmental considerations is a logical step forward.

25   Arguments in support of this approach include the use made of traditional accounting systems for

26   analysis and forecasting, as well as policy formulation. First, economic accounts are traditionally used

27   and it is argued that all economic activity should be taken into consideration. This includes the use of

28   the natural environment and its incorporation occurring alongside traditional accounting activities.

29   Second, there is the requirement for a consistent, reliable and comparable data set which can be used

30   for the effective management of the environmental resource base (Pearce et al., 1989a).   This is

4

1   particularly true regarding current interest in more sustainable farming systems, as the national accounts

2   exclude the environment and natural resource base which thus may encourage unsustainable levels of

3   production and consumption. Third, the accounting approach provides a framework for both farm level

4   analysis and subsequent macro level analysis and, given the current lack of research on practical

5   applications of accounting techniques to evaluating the environment, it is a method which merits further

6   exploration.

7

8   **3.   Methodology and Approaches**

9   *3.1. Integrated agriculture*

10   Integrated agricultural production has been defined by El Titi et al. (1993) as *An holistic pattern of*

11   *land use which integrates natural resources and regulation mechanisms into farming practices to*

12   *achieve maximum but stepwise replacement of off-farm inputs to secure quality food and to sustain*

13   *income.*

14   IAFS have attracted a great deal of research interest in the UK. They have implications for the

15   management of farmland as they involve more complex and often longer rotations, changes in

16   cultivations (especially the adoption of non-inversion tillage) and a reduction in the level of both

17   pesticide and fertiliser use, if appropriate. Such practice is, in part, related to the aim of improving

18   habitats and thus biodiversity at the whole farm level, which clearly would influence the decision-

19   making processes related to husbandry practices and expectations of financial rewards on farms (Park et

20   al., 1997).

21

22   *3.2. The experiment at Pathhead farm*

23   Pathhead farm is some 15km south-east of Edinburgh, Southern Scotland (latitude 56°N) on

24   loam/clay loam soils of the Winton Association. The mean 30-year rainfall is 860mm per annum. Full

25   details of the experiment are provided by Fisher et al. (1996).

26   The conventional crop rotation at the farm reflected standard commercial farming practice in the local

27   (Lothian and Borders) region in the early 1990's namely: winter oilseed rape (*Brassica rapus*) (phase

28   1), winter wheat (*Triticum aestivum*) (phase 2), set-aside (phase 3), winter wheat (phase 4), and winter

29   barley (*Hordeum vulgare*) (phase 5). The integrated rotation is spring oilseed rape (phase 1), winter

30   wheat (phase 2), set-aside (phase 3), winter wheat (phase 4), and spring barley (phase 5). The main

1   difference between the two systems is that the integrated system had spring, rather than winter, oilseed

2   rape in phase 1 of the rotation and spring barley instead of winter barley in phase 5.

3   The change to spring cropping enabled savings in nitrogen fertiliser use from some 160kg ha^{-1} under

4   the conventional rotation to around 120kg ha^{-1} on the integrated rotation. Similarly, the more careful

5   use of pesticides under the integrated system led to a reduction in active ingredient applied from 2.81 to

6   1.55kg ha^{-1} (Fisher et al., 1996).

7

8   *3.3. Application to the appraisal of Integrated Arable Farming Systems*

9   The framework for the environmental and natural resource accounting model needs to incorporate two

10   perspectives for the evaluation of IAFS: the financial account for agricultural production activities and

11   a parallel account for environmental impact. These then need to be combined within an integrated

12   environmental and economic account to illustrate the traditional financial impact of conventional farm

13   practices and IAFS alongside their environmental impacts.

14

15   *3.3.1. Financial data*

16   The output from agriculture is conventionally measured in financial terms. Farm income, or profit, on

17   arable farms is a function of yield, crop price, area payments, and the costs directly influenced by

18   management variables such as input choices and levels of fertiliser and pesticide use and cultivation

19   practices. Conventional farm accounts are, therefore, the main criteria for measuring the financial

20   viability of agricultural systems. However, for a thorough analysis of the productivity of agricultural

21   systems the effect of the economic environment, markets and subsidies, natural environment,

22   particularly climatic conditions, and social environment also need to be taken into consideration in the

23   use of these accounts.

24

25   *3.3.2. Environmental data*

26   Identifying criteria to illustrate the impact of agriculture on the environment is more problematic.

27   They need to be measurable, derived objectively, verifiable, and replicable and, given that it is currently

28   impossible to measure all environmental impacts, they should ideally be proxies for other processes.

29   Indicators which measure changes in key processes or highlight areas of concern are commonly used.

30   Areas of concern include changes in: amenity; soil quality; water quality and quantity; atmospheric

quality; and habitat and wildlife as a result of land use and chemical inputs. Concern about energy use may also be considered as an environmental issue.

At the individual farm level, important indicators include the amenity and landscape value associated with the farming system, the impact on soil quality through the direct use of the land resource, the impact of chemical use, i.e., fertilisers and pesticides, and the resultant impacts on water quality (resources), atmosphere and biodiversity. Given that data on the amenity aspects of both the conventional and integrated systems of the LINK IFS project have not been recorded, with the assessments concentrating on the within-field aspects, this paper will now concentrate on the latter indicators which reflect, loosely, the three main economic functions of the environment: as a source of raw materials; as a sink for waste assimilation; and as a provider of environmental services.

3.3.2.1. The environment as a source of raw materials

Soil is the main physical medium for agriculture and is the site of many complex transformation processes. Assessment of soil quality regarding the demands made on this resource over time is important and should cover physical, chemical and biological criteria. Examples of indicators that are used to assess soil quality include organic matter, acidity and the levels of phosphorous, potassium, and heavy metals in the soil (e.g., Department of the Environment, 1996). Bio-indicators such as invertebrates and, in particular, earthworm numbers and/or biomass can also be used. Such data were collected in the LINK IFS experiment. Earthworms are important to soil fertility and structure as they play a key role in trash burial, nutrient cycling, soil aeration and drainage (Lee, 1985). They are also a useful indicator as they are sensitive to a range of short-term agricultural activities (Edwards and Lofty, 1972; Edwards and Bohlen, 1996).

The economic value of earthworms is a problem, but potentially solvable as there is an actual open market value for earthworms based on their costs of production. Alternatively, as the market price may be considered a high estimate, a value could be derived by econometric techniques to extract the effect that earthworms have on crop output, through their influence on soil quality. A problem with this approach is that it is considered more appropriate to *crops planted into soil that has not been cultivated* (Edwards and Bohlen, 1996). However, a provisional estimate may be obtained using the difference in cost between ploughing and minimal tillage practices, assuming that the difference equates to the value

1   of the soil structuring service provided by earthworms. It is recognised that this is only an estimate and

2   that ploughing enables rates of trash burial, mineralisation and aeration far in excess of that achievable

3   by earthworms in a season.

4

5   *3.3.2.2. The environment as a sink for waste assimilation*

6   Concerns regarding water quality include chemical, biological and physical aspects and are

7   highlighted in the criteria for the 1985 River Quality Classification (Department of the Environment,

8   1986), which include dissolved oxygen, biological oxygen demand (BOD), ammonia, toxicity to fish,

9   and visible signs of pollution. Additional indicators include nitrate and pesticide use, nitrate,

10 phosphorous and pesticide concentrations in water, pollution incidents, and water treatment expenditure

11 (e.g., Department of the Environment, 1996; OECD, 1997).

12 Nitrogen fertiliser is an important agricultural input, vital to the growth of plants in terms of both the

13 quantity and quality of yield. Its impact on surface and groundwater through nitrate leaching has

14 become a major environmental issue over the last decade (see Addiscott et al., 1991), and it is

15 acceptable to use nitrate levels as an indicator to estimate the environmental impact of agricultural

16 systems on water quality. Nitrate residues in the soil after harvest (autumn) provide a measure of

17 leaching risk. In order to calculate the economic value of nitrate lost from the system, it is assumed that

18 all the residue in the soil is leached from the system. The environmental damage cost incurred as a

19 result of this leaching is then taken to be equal to the costs of treating the pollution. The cost incurred

20 should not be applied to every kilogram of nitrate lost from the system, but to that above a threshold

21 level as there is some naturally occurring leakage of nitrate from the soil irrespective of management

22 practice. The environment also has the potential to assimilate some waste without damage being

23 incurred.

24 Pesticide levels are another indicator of environmental impact on water quality. Concern regarding

25 their use and effect on both human health and the environment has recently increased. However, there

26 is little work on the quantities of pesticide applied in relation to the amounts occurring in water sources

27 so it is more appropriate to concentrate on the actual level of pesticide use. Both direct and indirect

28 impacts need to be considered; direct impacts on target and non-target flora and fauna, and indirect

29 impacts where pesticides are caught up in the food chain affecting species further along that chain. The

economic value of this indicator is problematic, although it could be related to the effect of the chemical on biodiversity.

3.3.2.3. The environment as a provider of services

Biodiversity, an increasingly important indicator of environmental quality, is a measure of the number of different species present within a given area, taking into account the number of representatives of each species present and the variety of habitats that exist within that area. Measures of biodiversity include the percentage of species at risk, number and population changes in important species groups, and a consideration of habitats (Department of the Environment, 1996; OECD, 1997).

To assess individual farms and particular agricultural practices, it is important to choose an indicator representative of those practices. Usual indicators include the number and population changes in mammals, birds and butterflies appropriate at the whole farm level. For the LINK IFS experiment, which is comparing two systems within a single field, an indicator which is relatively immobile and, affected by specific within field differences is more appropriate. Data on the number of invertebrates caught by pitfall traps within each experimental plot are used as one indicator in the LINK-IFS experiments. These can be considered as relevant indicators as they are part of a complex food web. In terms of the economic valuation of biodiversity (Spash and Hanley, 1994; Hanley et al., 1994) there are few applications in the UK all involving the use of the contingent valuation method (CVM). Related to this is the Delphi technique, an established mechanism for collecting expert opinion, which can be very effective in acquiring information on values from participants who possess technical knowledge. It also has the advantage that it can be undertaken in a short time period relatively cheaply. An alternative approach is to relate the value of beneficial insects to the cost saving from reduced pesticide use. This assumes that pesticides are a replacement for natural ecosystem resilience.

4. Results

Using data from one of the sites in the LINK IFS experiment, the accounting framework is used here to compare the impact of conventional and integrated arable farming systems on financial returns and the environment. As stated in the introduction, this is a five year rotational systems experiment, with each phase of the rotation represented in every year. The data presented include both traditional financial results and the environmental data.

1

2 *4.1. Financial results*

3   Table 1 provides a summary of the financial results for the five years of the experimental rotation at

4 the Pathhead site in Southern Scotland. Output is calculated by multiplying the yield by the average

5 November price (from the HGCA Weekly Digest) for each crop in each year plus the area payment for

6 that year. Costs, which were already standardised as part of the main LINK-IFS project, are based on

7 material supplied by Mr D. Harris, ADAS (Personal Communication). The aim of these results is to

8 reflect the value of agricultural production to the farmer. They show that, in traditional financial terms,

9 the integrated system does marginally better than the conventional system over the five years of the

10 rotation shown with gross and net margins per hectare of £3840 and £2921 respectively. Output is

11 lower, a result of substantially lower yields in the spring rape crop, and occasionally slightly lower

12 yields in the cereal crops. However, the total variable costs are also lower, mainly as a result of

13 reductions in chemical use. Cultivation costs are also lower. These lower costs give rise to the better

14 gross and net margins on the IAFS.

15   Table 2 presents the same information using world prices (mid-November prices from the HGCA

16 Weekly Digest) and without area payments to reflect the social value of agricultural output from the two

17 systems via the removal of government intervention. Phase 3, set-aside, is also excluded from the

18 rotation. In using world prices, it is assumed that the use and subsequent management of inputs into the

19 two systems remains unchanged, and that crop choice, despite changing prices, also remains unchanged.

20 Furthermore, using world prices for crop products and not for crop inputs may provide an overestimate

21 of output where there are tariffs and subsidies on the imports of inputs. Nevertheless, given the

22 problem in determining the combination of inputs in the absence of support, the use of world prices

23 alongside the exclusion of area payments to provide the social value of agricultural output is a

24 reasonable assumption. This results in a lower gross margin for the integrated system compared with

25 the conventional system, and a smaller difference between the two for the net margin.

26

27 *4.2. Environmental results*

28   The subsequent tables provide information on the environmental data being considered. These

29 include information on the causes of environmental degradation, i.e., the use of nitrogen fertiliser and

30 pesticides (Table 3), and the effects that these are believed to generate. The indicators chosen to

1   represent these impacts are, respectively, earthworm (*Lumbricidae*) biomass (Table 4), nitrate loss

2   (Table 5), and invertebrate (beetle (*Carabidae*)   and spider (*Arachnida*)) numbers (Table 6).

3   Cultivation practices at the Pathhead site, a further cause of impact on the environment, are unchanged

4   between the two systems. In terms of the economic valuation of the environmental impact of the two

5   systems, it is only the latter indicators themselves that would need to be valued, the causes of those

6   impacts (cultivation practices and chemical use) indicating only the potential impact.

7

8   *4.2.1. Chemical use*

9   Data on the use of chemicals in both the conventional and integrated system were recorded for each

10   plot at the time of application, the overall aim being to reduce these inputs where appropriate. In the

11   conventional system, nitrogen was applied according to conventional farm practice (i.e., farm

12   manager's rate). For the integrated system, Scottish Agricultural College (SAC) recommendations were

13   used, reduced for those fields where February mineral N measurements were high. In latter years, the

14   correction for soil mineral N was halted as validation trials showed that the integrated rate was

15   consistently too low to maximise profit. Nevertheless, applications for comparable wheat crops on the

16   integrated system were always lower than on the conventional. Applications were also lower for the

17   spring crops. SAC recommendations were used for P and K applications throughout, reductions

18   occurring on the integrated system where spring crops replaced winter crops.

19   In relation to the use of pesticide, cereal crops on the integrated system were chosen for their disease

20   resistance, with the use of fungicides being modified accordingly. Routine spraying was carried out on

21   the conventional system. The same is true for herbicide applications, there being no use of autumn

22   residual herbicide on the integrated wheat crops, whereas the conventional wheat had one application

23   when soil conditions allowed access. Insecticides were generally not used on either system. The

24   conventional wheat crop had routine treatment for slugs following winter oilseed rape; this was not

25   needed for the wheat following the spring rape crop, although some spot treatment was used as

26   necessary.

27   Table 3 summarises the chemical use in both systems. As is to be expected, it shows that the use of

28   nitrogen fertiliser on the integrated system in comparison with conventional practice is reduced. This is

29   primarily as a result of the inclusion of spring crops in the rotation, although as stated above,

30   applications on the winter wheat crops are also reduced. Table 3 also shows the number of pesticide

1 units used in each system, a unit being the maximum amount (in grams) of an active ingredient

2 recommended for arable crops. As outlined above, reductions in the use of all pesticides are achieved

3 for all chemicals (except seed dressings) in all years and for all crops on the integrated rotation with few

4 exceptions.

5

6 *4.2.2. Earthworm biomass*

7 Table 4 presents information on earthworm biomass changes at the Pathhead site. The fact that the

8 experiments were carried out at a field scale means that starting values were inevitably different – this is

9 difficult to overcome in this type of systems experiment. Data regarding earthworms are only available

10 for 1992 (samples were taken before the start of the experiment) and 1995 and 1997 (samples were

11 taken prior to the harvesting of that year's crop). It should be noted that the cultivations, considered an

12 important factor with regard to effects on soil fauna (Edwards, 1984), are the same on both the

13 conventional and integrated systems at Pathhead. Other sites have opted for non-inversion tillage on

14 their integrated plots where possible, a practice which is believed to be less detrimental to earthworm

15 populations. Nevertheless, this status quo in terms of cultivation practices at Pathhead does not explain

16 the increase in earthworm biomass on the conventional system compared with the small reduction in

17 overall biomass on the integrated system. However, these differences could perhaps be explained by

18 changes in the amount of organic material returned to the soil under the two systems given the

19 differences in crop output. Differences that are apparent are the increase and higher earthworm biomass

20 in the set-aside phases after wheat in both systems; the lowest earthworm biomasses occur in the wheat

21 and oilseed rape phases of the rotations.

22 In determining the economic value of earthworms, it is assumed that the agricultural use value of

23 earthworms in terms of soil quality equates to the difference between the cost of ploughing and

24 subsequent cultivation and minimal tillage practices including direct drilling. The relevant costs per

25 hectare are £90 for ploughing including the associated seedbed preparation, between £40 and £80 for

26 minimal tillage, and £30 for direct drilling (Nix, 1996). The difference between the two practices

27 therefore ranges from £10, the difference between ploughing and the most costly minimal tillage

28 system, to £60 the difference between ploughing and direct drilling. To equate this to changes in

29 earthworm biomass a baseline population is required. In certain circumstances, earthworms are bought

30 in and inoculated into the soil via the use of soil plugs, although on agricultural land this appears to

1   have only occurred during the periods of reclamation of land for permanent grassland. Where soil

2   plugs, containing approximately 0.1 kg of earthworms, are bought in, the maximum number of plugs

3   that would be used per hectare would be 1250 thus giving rise to, based on a zero population of

4   earthworms at the outset, an earthworm biomass of 125 kg. This can be taken as the baseline amount

5   required. Dividing the difference in cost between ploughing and drilling (£60) by the baseline

6   earthworm biomass required in terms of basic soil structuring requirements (125 kg) gives a value of

7   £0.48 per kilogram of earthworm. Alternatively, taking the lower value of £10, the difference between

8   ploughing and minimal tillage, gives a value of £0.08 per kilogram of earthworm. Taking the changes

9   per hectare in each of the two systems between 1992 and 1995, i.e. an increase of 308 kilograms on the

10   conventional and a reduction of 278 kilograms on the integrated, gives an additional benefit of £147.84

11   and damage cost of £133.44 respectively at the higher value, or a benefit of £24.64 and damage cost of

12   £22.24 at the lower value.

13

14

15   *4.2.3. Nitrate loss*

16   Table 5 provides information on the nitrate residues at Pathhead from samples taken at a depth of

17   90cm in the autumn of each year. Data for this are only available for 1995, 1996 and 1997 as no

18   autumn sampling was undertaken in 1993 and 1994. The data indicate excess nitrate in the soil which

19   runs the risk of loss from the system over the winter period. As can been seen from the data, residues in

20   the conventional system are greater than that on the integrated system. Substantial differences occur,

21   first, after set-aside in 1995 favouring the integrated system, although in the following year after winter

22   wheat the reverse is true; and second, after oilseed rape in all three years. A notable difference also

23   occurs in 1995 and 1996 between the barley crops of the two systems. Winter oilseed rape on the

24   conventional system has the highest residues in all years, whereas in the integrated system the highest

25   residues occur in the wheat phases. The lowest residues tend to be in the set-aside and barley phases of

26   both systems.

27   The economic value of these nitrate residues, all of which are assumed to have been leached into

28   surface or groundwater courses, can be related to the damage it causes to water quality and the cost of

29   reparation of that damage. In the case of ground water this equates to the cost of removal of nitrates

30   from the water when it is abstracted for drinking water. In the case of surface water, this equates to the

1   cost associated with the damage to commercial fish stocks as a result of eutrophication although

2   estimates of this value may be more difficult to calculate.

3   An initial value, based on ground water costs only, is determined from United States data (Panel on

4   Nitrates, 1978) converted to pounds sterling per kilogram and updated for inflation but not for advances

5   or differences in UK technology. The Panel on Nitrates (1978) provide five estimates regarding the

6   removal of nitrates from polluted water based on different approaches to treatment. Taking the average

7   treatment cost of three of the approaches (denitrification, chlorination, and ion exchange), which are

8   similar in cost and also in the effectiveness of removal of nitrate (70-95%), gives rise to an average

9   treatment cost of £2.49 per kilogram of N. Two other processes are ignored, nitrification and

10 electrodialysis, as they remove less than 50% of the nitrate within the water. This treatment cost can

11 then be applied to the nitrate residues. However, the cost is not applied to all the available residue but

12 to levels above a given threshold. This recognises that there is some naturally occurring leakage of

13 nitrate from the system, and also that that the environment has the ability to assimilate a certain amount

14 of waste in the form of pollution before it becomes adversely affected. Two thresholds have been put

15 forward. First, a threshold of 4kg which has been suggested as the maximum amount of leakage that

16 occurs from undisturbed natural ecosystems (Gosz, 1981; Melillo, 1981). Second, threshold levels

17 which relate the losses of nitrate residues to the concentrations in the receiving water using the EU limit

18 as a reference point, concerns over drinking water quality having led to the European Community

19 imposing a limit of 50 mg l^{-1} for nitrate in potable water (Council of the European Communities, 1980).

20 Concentrations above this limit incur a cost, whereas concentrations below this limit do not incur a cost.

21 The limit used, although arbitrary, can be justified in that it is a well-documented, recognised, legalistic

22 reference point and is a value which has received considerable attention regarding the relationship

23 between nitrate loss and the resultant concentrations in the receiving water in relation to soil type,

24 climate and the quality of that receiving water. Williams (1990), for example, has modelled nitrate loss

25 in relation to the concentrations in the receiving water using data on the water supply system, the

26 process of nitrate leaching and farming land use. Included in the calculations are data on rainfall, soil

27 type and rock strata, and water volume, abstraction, flows and hydrological pressure. This model has

28 provided three ranges of maximum nitrate loss allowable to meet the EU limit: 11-22kg for the area

29 around East Anglia; 22-33kg for North East England, the Midlands, the South East, and the far eastern

30 half of East Anglia; and 33-45kg for Scotland, Wales, the North West and South West. It is the lower

1 bound estimates that are used as thresholds in this analysis; for the Pathhead site in Scotland this allows

2 a loss of 33kg of nitrate before a cost is incurred. Therefore, in the conventional rotation at Pathhead

3 during 1995, assuming a loss of 60kg (93kg minus 33kg allowable), the cost of the resultant damage

4 would be £149.40.   Similarly, for the integrated rotation in that year the cost would be £72.21.

5 Alternatively, with a threshold of 4kg, the cost would be £221.61 for the conventional system and

6 £144.42 for the integrated system.

7

8 *4.2.4. Beetle and spider numbers*

9 Table 6 provides information on the final indicator of environmental impact, the number of

10 invertebrates (*Carabidae, Staphylinidae, Linysiidae, Lycosidae*) within each system. In each field, and

11 for both farming systems, two transects of five pitfall traps were used to collect data on invertebrate

12 activity. The traps were placed 30m in from a common boundary and then spaced at 10m intervals

13 thereafter. The pitfall traps were partly filled with water and detergent and operated for 10 day periods

14 during the winter and 5 day periods during the summer for the length of each crop's growing period.

15 The results show that there is no obvious pattern in either system, with the integrated system in

16 comparison with the conventional showing marginally higher numbers for four years and lower

17 numbers in one year. The more obvious pattern is the swing between increases and reductions across

18 the years in both systems, and there is some indication that the set-aside phases lead to greater

19 invertebrate numbers, whereas oilseed rape gives rise to the least numbers.

20 In terms of their economic value, an estimate could be based on information on pesticide costs

21 assuming that the invertebrates are of quantifiable value to the individual farmer as a natural predator of

22 crop pests such as aphids, and that an increase in their number will reduce the farmer's reliance on

23 pesticides and as a result pesticide costs. To do this, the average cost of application of an insecticide

24 needs to be given and equated with a baseline population of beneficial invertebrates required to replace

25 that insecticide. Dividing the number in the required baseline population by the cost of the pesticide

26 would give a measure of invertebrate value. This should realistically be based on a population per one

27 hundred or one thousand, the resultant value being applied to changes (flow values) in that population

28 as opposed to static (stock) numbers. Although data are available on insecticide costs - an appropriate

29 value would be £15 per hectare (Nix (1996), taking the cost of an insecticide containing the active

30 ingredient pirimicarb, estimates the approximate cost of an application from £13-15 in cereals and from

1   £15-22 in oilseed rape) - the information on the baseline number of invertebrates is not. Furthermore,

2   relating the number of invertebrates caught in pitfall traps (a measure of activity) to a given population

3   per hectare is not possible. A similar approach based on their value as part of the food chain would also

4   require an estimate of numbers related to population as opposed to activity. Given the current difficulty

5   in providing a suitable estimate of value, a record of the physical numbers caught in pitfall traps is

6   presented. Individuals may wish to make a subjective decision about the trade-offs between this

7   indicator (biodiversity), financial returns, earthworm biomass (soil quality) and nitrate loss (water

8   quality).

9

10   **5. Discussion and conclusions**

11   Combining the information on the financial results with environmental impact gives rise to a system

12   of integrated environmental and economic accounts (see Table 7). It indicates both the financial and

13   environmental values for the five years of the experimental rotation at the Pathhead site. First, the

14   traditional financial account is given, showing that the integrated system, in this example, is financially

15   viable when compared to conventional farming practices in that it has a higher net margin. Second, the

16   values for the environmental impact are included. In this example, the minimum environmental values

17   given previously (see sections 4.2.2., 4.2.3. and 4.2.4.) are used. Counter-intuitively, in environmental

18   terms, the integrated system appears to be less beneficial to the environment in terms of soil quality

19   (earthworm biomass), and the results are inconclusive for the effect of the two systems on fauna

20   (invertebrate numbers). These indicators suggest that although inputs into the environment can be

21   measured directly at the time of occurrence, the impacts that may then indirectly arise from those inputs

22   may take a longer time to materialise. However, nitrate residues, used as an estimate of potential

23   leaching, are an indicator that provides results that would be expected, with the integrated system

24   appearing less damaging in terms of water quality. Overall, both the conventional and integrated

25   margins are reduced as a result of environmental impacts, although the difference between the two

26   systems increases indicating that the integrated system, despite its negative impact on earthworm

27   biomass, is of greater benefit to the environment than when compared with the conventional system.

28   Despite these observations, statistical analysis of the data using analysis of variance reveals that there is

29   no significant difference between the two systems with respect to Net Margins, beetles and spiders,

30   earthworms and nitrate residues (see Table 8). Dealing with the impact of earthworm biomass on the

farming system in order to extract the statistical significance from the results poses a problem. The quantitative information available on earthworm interaction with other components of the system is insufficient, particularly in terms of time series. Thus, it would not be wise to attempt to draw firm conclusions from the above analyses, other than to accept that at this stage the aim has been to develop a method of comparison not necessarily to obtain absolute values.

Regarding the use of environmental and natural resource accounting it can be said that it has the potential to provide a format for allowing the trade-off between financial and environmental impacts, and between the differing environmental impacts themselves. The example given above illustrates the application of the accounting framework to the comparison of different farming systems, achieved through the definition of the costs and benefits of agri-environmental measures, both positive and negative. The above proposed framework is also flexible enough to incorporate data regarding other environmental impacts as they become available and, even without complete valuation, presents the data in a format which can aid the understanding of agricultural and environmental trade-offs.

Considering the indicators used, it should be noted that the earthworm data relates to agricultural use values only. Non-use / intrinsic values would need to be included to give a more accurate estimate of their value; the approach to the calculation of these values would perhaps involve the use of CVM (Cummings et al., 1986) or consultation with experts using the Delphi technique. Such techniques may also be useful in overcoming the problem of the valuation of biodiversity using the data on invertebrates. Values for the use of nitrates are already reflected in the accounts as the additional input costs for nitrogen fertiliser. The figures calculated for the treatment cost of polluted water represent the additional cost to society of that pollution. A limitation concerning the use of such indicators to assess the environmental impacts of agricultural production systems is that the choice of indicator may inevitably lead to some form of bias, favouring one or other of the systems under review. This, of course, depends on the nature of the indicators used, and is a problem which is also applicable to other methods which use similar approaches to examine environmental impact. A final limitation of the approach are the problems, highlighted by the information on invertebrates, regarding the provision, measurement and valuation of data.

Nevertheless, the above approach has the potential to provide insights for both farm level decision making and macro level policy formulation, and is of particular relevance to sustainable farming systems where the objectives are to achieve long term financial viability with minimal adverse impacts

on the environment. Furthermore, although the current version of the model is only suitable for short-term static analysis, given additional data, the longer term implications of both conventional and integrated arable systems could be evaluated. Even without this additional data, the process of recording and valuing the environmental information as it becomes available can provide valuable insights regarding the impacts of differing agricultural systems on the environment.

7

1   Table 6

2   Comparison of mean number of invertebrates (beetles and spiders) per pitfall trap per day over the crop

3   growing period at the Pathhead, Scotland site for the conventional and integrated systems, 1992-1997

	CFS [a]	IFS [b]
Number of invertebrates		
1992	1.50	1.52
1993	0.55	0.64
1994	5.41	5.22
1995	0.96	1.21
1996	1.37	1.52
1997	1.17	1.29
Change in the number of invertebrates		
1992-1993	-0.95	-0.88
1993-1994	+4.86	+4.59
1994-1995	-4.45	-4.02
1995-1996	+0.41	+0.31
1996-1997	-0.20	-0.23
1992-1997	-0.33	-0.23

4   [a] Conventional farming system.

5   [b] Integrated farming system.

7

1   Table 7

2   Comparison of financial and economic results (£ ha^{-1}, current prices) at the Pathhead, Scotland site for

3   the conventional and integrated systems, 1992-1997

	Rotation	
	CFS [a]	IFS [b]
Output	4850.50	4610.80
Seed costs	215.90	223.40
Fertiliser	449.48	354.89
Pesticides	319.04	147.60
Other variable costs	46.00	46.86
Total variable costs	1030.46	774.19
Gross margin	3820.07	3836.61
Operating costs	988.71	918.48
Net margin	2831.36	2918.13
Earthworm biomass	+28.88	-9.92
Nitrate loss [c]	-674.79	-448.20
Environmentally adjusted net margin	2185.45	2460.01
Invertebrate numbers	*-0.33*	*-0.23*

4   [a] Conventional farming system.

5   [b] Integrated farming system.

6   [c] Figures for 1995-1997 only.
