ABSTRACT

A nonlinear stability theorem is established for Eady's model of baroclinic flow. In particular, the Eady basic state is shown to be nonlinearly stable (for arbitrary shear) provided

$$\frac{\Delta z}{\Delta y} > \frac{2\sqrt{5}f}{\pi N},$$

where Δz is the height of the domain, Δy the channel width, f the Coriolis parameter, and N the buoyancy frequency. When this criterion is satisfied, explicit bounds can be derived on the disturbance potential enstrophy, the disturbance energy, and the disturbance available potential energy on the rigid lids, which are expressed in terms of the initial disturbance fields. The disturbances are completely general (with nonzero potential vorticity) and are not assumed to be of small amplitude. The results may be regarded as an extension of Arnol'd's second nonlinear stability theorem to continuously stratified quasigeostrophic baroclinic flow.

1. Introduction

There has been considerable recent interest in the derivation and application of nonlinear stability theorems to quasigeostrophic baroclinic flow. These theorems apply to inviscid, unforced flow and rely on certain exact nonlinear conservation laws, which are associated with the underlying Hamiltonian structure of the dynamics (e.g., Shepherd 1990). For example, by using a suitable combination of momentum and Casimir invariants, a finite-amplitude generalization of the Charney–Stern theorem can be obtained for both layered and continuously stratified flow (Shepherd 1988, 1989). Using a combination of energy and Casimir invariants provides a finite amplitude generalization of the Fjørtoft–Pedlosky theorem (Holm et al. 1985; Swaters 1986; McIntyre and Shepherd 1987; Zeng 1989): this may be regarded as an extension of Arnol'd's (1965, 1966) first nonlinear stability theorem to quasigeostrophic flow.

The mathematical method behind the above-mentioned results consists of the construction of a conserved functional, whose first variation at the basic state is zero and whose second variation is sign definite for arbitrary perturbations. The basic state is then an extremum of the conserved functional and is therefore stable. This variational argument was originally introduced by Fjørtoft (1950) and appears to be inherently a small amplitude technique. However, it was realized by Arnol'd (1966), in considering the two-dimensional Euler equations, that in many cases of interest *all* the higher-order contributions to the functional may be bounded a priori, in which case the stability is in fact nonlinear. It turns out that this insight applies to the quasigeostrophic equations, among others (see above references).

Arnol'd's first stability theorem corresponds to cases where the second variation of the energy–Casimir invariant is positive definite, while the second theorem corresponds to cases where it is negative definite. Establishment of analogues of the first theorem is generally straightforward, but the second theorem turns out to be much more delicate. The difficulty has to do with showing that the positive part of the energy–Casimir invariant is smaller in magnitude than the negative part; this involves the use of a Poincaré inequality, which depends heavily on the presumed boundary conditions. For example, a straightforward extension of Arnol'd's second theorem to continuously stratified flow requires

* The results of this paper were announced as part of an extended abstract by Mu and Shepherd (1992).

that the disturbance have zero circulation on the side-walls and zero temperature perturbation at the rigid lids [McIntyre and Shepherd (1987), appendix B]: a significant restriction indeed!

The quasigeostrophic analogue of Arnol'd's first theorem, for zonally symmetric flow, requires that $U/Q_y < 0$ in some frame of reference; here U is the zonal velocity and Q_y the meridional gradient of potential vorticity. However, as pointed out by Andrews (1984), most geophysically relevant flows are "pseudoeastward," in the sense that $U/Q_y > 0$, which takes them into the realm of Arnol'd's second theorem. Of course, one is allowed to choose the frame of reference, and in this way Arnol'd's first theorem may be usefully applied to the Phillips model of baroclinic instability (Shepherd 1993). But with rigid lids, this device is not useful: when interpreting surface temperature gradients as concentrated potential vorticity gradients, in the sense described by the Charney–Stern theorem, it is clear that the Eady basic state cannot be brought into a "pseudowestward" configuration by a change of reference frame. In this case, therefore, one has no choice but to deal with Arnol'd's second theorem directly.

In the case of two-dimensional flow, Mu (1992) and Mu and Shepherd (1994) have recently succeeded in obtaining nonlinear stability criteria analogous to Arnol'd's second theorem. Related results have been obtained for multilayer quasigeostrophic flow by Mu et al. (1994). The purpose of this paper is to establish a corresponding result for Eady's model of quasigeostrophic baroclinic flow. The work builds on methods developed by Mu and Zeng (1991) and Mu and Wang (1992). When the stability criterion is satisfied, rigorous upper bounds may be derived on the potential enstrophy, the energy, and the boundary available potential energy of finite-amplitude disturbances to the Eady basic state. Unlike the usual normal-mode analysis of the Eady problem, the disturbances considered herein are arbitrary and in particular may have nonzero potential vorticity. The upper bounds hold uniformly in time, are expressed in terms of the initial disturbance fields, and tend to zero uniformly as the initial disturbance amplitude decreases to zero. It follows that the bounds establish nonlinear stability of the Eady basic state.

2. Statement of the problem

Consider three-dimensional continuously stratified quasigeostrophic flow on an f plane, governed by the model

$$\frac{\partial P}{\partial t} + \partial(\Phi, P) = 0 \quad \text{in } \Omega, \quad (2.1a)$$

$$\left\{ \frac{\partial \Phi_i}{\partial t} + \partial(\Phi, \Phi_i) \right\} \Big|_{z=z_i} = 0 \quad \text{in } D \quad [i = 0, 1].$$

(2.1b)

Here $\Phi(x, y, z, t)$ is the streamfunction, and

$$P = \nabla^2 \Phi + \frac{1}{S} \Phi_{zz} + f \quad (2.2)$$

is the potential vorticity; subscripts denote partial differentiation; f is the (constant) Coriolis parameter; $S = N^2/f^2$ is a (constant) static stability parameter, where N is the buoyancy frequency; x and y are eastward and northward coordinates, z the height coordinate, and t the time; $\partial(a, b) \equiv a_x b_y - a_y b_x$ is the two-dimensional Jacobian operator; and $\nabla^2 = \partial_x^2 + \partial_y^2$ is the two-dimensional Laplacian operator. The spatial domain is a zonal periodic channel

$$D = \{-X \leq x \leq X, -Y \leq y \leq Y\}, \quad \Omega = D \times (z_0, z_1), \quad (2.3)$$

with $0 \leq z_0 < z_1 < \infty$. The lateral boundary conditions on the channel sidewalls are

$$\frac{\partial \Phi}{\partial x} \Big|_{y=-Y, Y} = 0, \quad \frac{d}{dt} \left\{ \int_{-X}^X \frac{\partial \Phi}{\partial y} dx \right\} \Big|_{y=-Y, Y} = 0. \quad (2.4a, b)$$

The system defined by (2.1), (2.2), and (2.4) constitutes the usual Boussinesq f -plane quasigeostrophic equations (e.g., Pedlosky 1987). For convenience we take the (constant) reference-state density to be unity. It may be verified that the system has the following integral invariants:

energy

$$\mathcal{E}[\Phi] = \int_{\Omega} \frac{1}{2} \left\{ |\nabla \Phi|^2 + \frac{1}{S} (\Phi_z)^2 \right\} dx dy dz, \quad (2.5)$$

zonal impulse

$$\mathcal{M}[\Phi] = \int_{\Omega} y P dx dy dz - \frac{1}{S} \int_D y \Phi_z dx dy \Big|_{z=z_0}^{z=z_1}, \quad (2.6)$$

and functionals of the form

$$\mathcal{G}_i[\Phi] = \int_D G_i(\Phi_z) dx dy \Big|_{z=z_i} \quad [i = 0, 1] \quad (2.7)$$

(with $G_i(\cdot)$ being arbitrary functions), which are Casimir invariants for this problem (e.g., Shepherd 1990). Note that $\mathcal{M}[\Phi]$ differs from the zonal momentum $\int_{\Omega} u dx dy dz$ by Casimir invariants; the zonal impulse and zonal momentum are both related to the underlying zonal symmetry in the system (Shepherd 1990).

We now investigate the nonlinear stability of the Eady basic state $\Phi = \Psi = -\Lambda yz$, $U = -\Psi_y = \Lambda z$, $P = Q = f$, where Λ is any given constant. Let (ψ, q) denote a finite-amplitude disturbance to this steady basic state, namely

$$\Phi = \Psi + \psi, \quad P = Q + q, \quad \Phi_z \Big|_{z=z_i} = B_i + b_i, \quad (2.8)$$

with $B_i \equiv \Psi_z|_{z=z_i} = -\Lambda y$. It follows that

$$q = \nabla^2 \psi + \frac{1}{S} \psi_{zz}, \quad b_i = \psi_z|_{z=z_i}. \quad (2.9)$$

In the normal-mode stability problem, one normally takes $q \equiv 0$; however, we do not wish to impose such a restriction. From (2.1a) and the fact that Q is spatially uniform, the disturbance potential vorticity q satisfies

$$\frac{\partial q}{\partial t} + \partial(\Psi + \psi, q) = 0;$$

then with the boundary condition (2.4a), one obtains

$$\frac{d}{dt} Z(t) \equiv \frac{d}{dt} \int_{\Omega} \frac{1}{2} q^2 dx dy dz = 0. \quad (2.10)$$

Thus, the disturbance potential enstrophy $Z(t)$ is conserved in time: $Z(t) = Z(0)$. Our aim is now to find a condition under which the disturbance energy,

$$E(t) = \int_{\Omega} \frac{1}{2} \left\{ |\nabla \psi|^2 + \frac{1}{S} (\psi_z)^2 \right\} dx dy dz, \quad (2.11)$$

and the disturbance available potential energy on the rigid lids,

$$E_b(t) = \int_D \frac{1}{2S} \{ (b_0)^2 + (b_1)^2 \} dx dy, \quad (2.12)$$

can be bounded in terms of the initial disturbance fields, with the bounds decreasing to zero uniformly as the initial disturbance tends to zero. If this can be done, then the condition is evidently sufficient to establish nonlinear stability of the Eady basic state.

3. Nonlinear stability

a. Bounds on disturbance energy

In this subsection, we use the integral invariants of the dynamics to provide upper bounds on the disturbance energies $E(t)$ and $E_b(t)$. First, define the functional

$$\begin{aligned} \mathcal{H}[\Phi] = & \mathcal{E}[\Phi] - \alpha \mathcal{M}[\Phi] - \frac{1}{S} (\mathcal{C}_1[\Phi] - \mathcal{C}_0[\Phi]) \\ & - \int_{z_0}^{z_1} \left\{ \Psi \int_{-x}^x \frac{\partial \Phi}{\partial y} dx \right\}_{y=-Y}^{y=Y} dz, \end{aligned} \quad (3.1)$$

where α is a constant to be determined later. Since \mathcal{H} consists of a combination of exact invariants together with a term involving the sidewall circulations, which are conserved according to (2.4b), it follows that \mathcal{H} is itself conserved in time. Now define the disturbance functional

$$H(t) = \mathcal{H}[\Psi + \psi] - \mathcal{H}[\Psi], \quad (3.2)$$

which is also an invariant of the motion and which

vanishes for zero disturbance. If we take the arbitrary functions $G_i(\cdot)$ in the definition of \mathcal{C}_i to be given by

$$G_0(\xi) = \frac{\Lambda z_0 - \alpha}{2\Lambda} \xi^2, \quad G_1(\xi) = \frac{\Lambda z_1 - \alpha}{2\Lambda} \xi^2,$$

then it follows that

$$G_i(B_i + b_i) - G_i(B_i) = G'_i(B_i) b_i + \frac{1}{2} G''_i(B_i) (b_i)^2 \quad (3.3)$$

with

$$G'_i(B_i) = (\Psi + \alpha y)|_{z=z_i} \quad (3.4a)$$

and

$$G''_i(B_i) = \frac{\Lambda z_i - \alpha}{\Lambda}. \quad (3.4b)$$

Now using (3.2)–(3.4a), it can be shown (after integrating by parts to eliminate the sidewall circulation terms) that

$$H(t) = E(t) + A(t) + H_1(t), \quad (3.5)$$

where $E(t)$ is given by (2.11), and $A(t)$ and $H_1(t)$ are defined by

$$A(t) = - \int_D \frac{1}{2S} \{ G''_1(B_1) (b_1)^2 - G''_0(B_0) (b_0)^2 \} dx dy, \quad (3.6)$$

$$H_1(t) = - \int_{\Omega} (\Psi + \alpha y) q dx dy dz. \quad (3.7)$$

Now choose α such that

$$z_0 < \frac{\alpha}{\Lambda} < z_1. \quad (3.8)$$

With α satisfying (3.8), it follows that

$$\begin{aligned} G''_0(B_0) = -c_0 & \equiv -\frac{\alpha - \Lambda z_0}{\Lambda} < 0, \\ G''_1(B_1) = c_1 & \equiv \frac{\Lambda z_1 - \alpha}{\Lambda} > 0, \end{aligned} \quad (3.9)$$

whence

$$A(t) = - \int_D \frac{1}{2S} \{ c_0 (b_0)^2 + c_1 (b_1)^2 \} dx dy, \quad (3.10)$$

which is negative definite. Now using the fact that $H(t) = H(0)$, we can write

$$-A(t) = E(t) + H_1(t) - E(0) - A(0) - H_1(0). \quad (3.11)$$

Equation (3.11) will provide the basis for the upper bounds on disturbance energy, as shown in detail below.

We note here the parallel, as well as the contrast, with Arnol'd's second stability theorem. The invariant functional being used is $H(t)$, which is not sign definite. Indeed, the first variation of $H(t)$ at the basic state is equal to $H_1(t)$, which is generally nonzero no matter how α is chosen. This is quite different from the usual nonlinear-stability methodology, where the invariant functional is specially constructed so that its first variation vanishes at the basic state. However, $H_1(t)$ will turn out to be boundable in terms of the initial disturbance [see (3.33)]. This leaves $A(t)$, which is negative definite, and $E(t)$, which is positive definite. The problem then reduces to finding conditions under which $E(t)$ can be bounded by $-A(t)$ plus terms depending only on the initial disturbance. If this can be done, then (3.11) can be rearranged to provide an upper bound for the positive definite quantity $-A(t)$. This is analogous to what is done in proving Arnol'd's second theorem (e.g., McIntyre and Shepherd 1987; Mu and Wang 1992).

To this end, define $\tilde{\psi} = \psi + \varphi$ where

$$\varphi(z, t) = \frac{\int_D (\psi_0 - \psi) dx dy}{\int_D dx dy},$$

$$\psi_0(x, y, z) = \psi(x, y, z, 0). \quad (3.12)$$

From the definition of $\tilde{\psi}$,

$$\frac{d}{dt} \int_D \tilde{\psi} dx dy = 0. \quad (3.13)$$

Since

$$\frac{d}{dt} \int_D q dx dy = 0 \quad \text{and}$$

$$\frac{d}{dt} \int_D b_i dx dy = 0 \quad [i = 0, 1], \quad (3.14)$$

we have that

$$\varphi_{zz} = 0 \quad \text{and} \quad \varphi_z|_{z=z_i} = 0 \quad [i = 0, 1]. \quad (3.15)$$

It follows from (3.15) that

$$\nabla^2 \tilde{\psi} + \frac{1}{S} \tilde{\psi}_{zz} = q \quad \text{and} \quad \tilde{\psi}_z|_{z=z_i} = b_i \quad [i = 0, 1]. \quad (3.16a, b)$$

Now multiply (3.16a) by $-\tilde{\psi}/2$ and integrate by parts over Ω , using (3.16b). Noting the inequality

$$ab \leq \frac{\epsilon a^2}{2} + \frac{b^2}{2\epsilon}, \quad (3.17)$$

which holds for any positive constant ϵ , this yields

$$\begin{aligned} & \int_{\Omega} \frac{1}{2} \left\{ |\nabla \tilde{\psi}|^2 + \frac{1}{S} (\tilde{\psi}_z)^2 \right\} dx dy dz \\ & \leq \frac{\epsilon}{4} \int_{\Omega} q^2 dx dy dz + \frac{1}{4\epsilon} \int_{\Omega} \tilde{\psi}^2 dx dy dz \\ & \quad + \sum_{i=0}^1 \left[\frac{\epsilon_i}{4} \int_D \frac{1}{S} (b_i)^2 dx dy + \frac{1}{4\epsilon_i} \int_D \frac{1}{S} \tilde{\psi}^2 dx dy \right]_{z=z_i} \\ & \quad + |H_*(t)|, \quad (3.18) \end{aligned}$$

where ϵ , ϵ_0 , and ϵ_1 are positive constants having the appropriate dimensions, to be determined later, and

$$H_*(t) = \frac{1}{2} \int_{z_0}^{z_1} \left\{ \tilde{\psi} \int_{-x}^x \frac{\partial \psi_0}{\partial y} dx \right\}_{y=-y}^{y=y} dz. \quad (3.19)$$

In obtaining the form of $H_*(t)$, the lateral boundary conditions (2.4) have been used.

From Mu and Wang [1992, Eqs. (2.19) and (2.20)], we have

$$\begin{aligned} \int_D \frac{1}{S} \tilde{\psi}^2 dx dy \Big|_{z=z_i} & \leq F(\chi) \int_{\Omega} \tilde{\psi}^2 dx dy dz \\ & \quad + \chi \int_{\Omega} \frac{1}{S} (\tilde{\psi}_z)^2 dx dy dz, \quad (3.20) \end{aligned}$$

where

$$F(\chi) = F_1 + \frac{F_2}{\chi}, \quad F_1 = \frac{1}{S(z_1 - z_0)}, \quad F_2 = \frac{1}{S}, \quad (3.21)$$

and χ is an arbitrary positive constant to be determined later. On the other hand, using (3.15) and integrating by parts yields

$$\int_{\Omega} \frac{1}{S} (\tilde{\psi}_z)^2 dx dy dz = \int_{\Omega} \frac{1}{S} (\psi_z)^2 dx dy dz,$$

whence

$$E(t) = \int_{\Omega} \frac{1}{2} \left\{ |\nabla \tilde{\psi}|^2 + \frac{1}{S} (\tilde{\psi}_z)^2 \right\} dx dy dz. \quad (3.22)$$

Using (2.10), (3.20), and (3.22), the inequality (3.18) becomes

$$\begin{aligned} E(t) & \leq \frac{\epsilon}{2} Z(0) + \left[\left(\frac{1}{\epsilon_0} + \frac{1}{\epsilon_1} \right) \frac{F(\chi)}{4} + \frac{1}{4\epsilon} \right] \\ & \quad \times \int_{\Omega} \tilde{\psi}^2 dx dy dz + \frac{\chi}{4} \left(\frac{1}{\epsilon_0} + \frac{1}{\epsilon_1} \right) \int_{\Omega} \frac{1}{S} (\tilde{\psi}_z)^2 dx dy dz \\ & \quad + \sum_{i=0}^1 \frac{\epsilon_i}{4} \int_D \frac{1}{S} (b_i)^2 dx dy + |H_*(t)|. \quad (3.23) \end{aligned}$$

To proceed further, we must bound $\int_{\Omega} \tilde{\psi}^2 dx dy dz$ by using the Poincaré inequality. To this end, let λ_2 be the least positive eigenvalue of the problem

$$\begin{aligned} \nabla^2 \phi + \lambda \phi = 0 \quad \text{in } D, \quad \frac{\partial \phi}{\partial x} \Big|_{y=-Y, Y} = 0, \\ \int_{-X}^X \frac{\partial \phi}{\partial y} dx \Big|_{y=-Y, Y} = 0. \end{aligned} \quad (3.24)$$

By the definition of $\tilde{\psi}$, together with (3.13) and (2.4b), we have

$$\int_D (\tilde{\psi} - \psi_0) dx dy = 0, \quad \int_{-X}^X \frac{\partial (\tilde{\psi} - \psi_0)}{\partial y} dx \Big|_{y=-Y, Y} = 0. \quad (3.25)$$

In light of (3.25) and the eigenvalue problem (3.24), the Poincaré inequality yields

$$\int_D (\tilde{\psi} - \psi_0)^2 dx dy \leq \frac{1}{\lambda_2} \int_D |\nabla (\tilde{\psi} - \psi_0)|^2 dx dy. \quad (3.26)$$

Integrating (3.26) in z then gives

$$\int_{\Omega} \tilde{\psi}^2 dx dy dz \leq \frac{1}{\lambda_2} \int_{\Omega} |\nabla \tilde{\psi}|^2 dx dy dz + H_{**}(t), \quad (3.27)$$

where

$$\begin{aligned} H_{**}(t) = \int_{\Omega} \left\{ \frac{1}{\lambda_2} (|\nabla \psi_0|^2 + 2|\nabla \psi_0 \cdot \nabla \tilde{\psi}|) \right. \\ \left. + (\psi_0)^2 + 2|\psi_0(\tilde{\psi} - \psi_0)| \right\} dx dy dz. \end{aligned} \quad (3.28)$$

Combining (3.23) with (3.27) results in

$$\begin{aligned} \left[\frac{1}{2} - \left(\frac{1}{\epsilon_0} + \frac{1}{\epsilon_1} \right) \frac{F(\chi)}{4\lambda_2} - \frac{1}{4\lambda_2\epsilon} \right] \int_{\Omega} |\nabla \tilde{\psi}|^2 dx dy dz + \left[\frac{1}{2} - \frac{\chi}{4} \left(\frac{1}{\epsilon_0} + \frac{1}{\epsilon_1} \right) \right] \int_{\Omega} \frac{1}{S} (\tilde{\psi}_z)^2 dx dy dz \\ \leq \frac{\epsilon}{2} Z(0) + \sum_{i=0}^1 \frac{\epsilon_i}{4} \int_D \frac{1}{S} (b_i)^2 dx dy + |H_*(t)| + \left[\left(\frac{1}{\epsilon_0} + \frac{1}{\epsilon_1} \right) \frac{F(\chi)}{4} + \frac{1}{4\epsilon} \right] H_{**}(t). \end{aligned} \quad (3.29)$$

Now let

$$M = \min \left\{ 1 - \left(\frac{1}{\epsilon_0} + \frac{1}{\epsilon_1} \right) \frac{F(\chi)}{2\lambda_2} - \frac{1}{2\lambda_2\epsilon}, 1 - \frac{\chi}{2} \left(\frac{1}{\epsilon_0} + \frac{1}{\epsilon_1} \right) \right\}, \quad (3.30)$$

and assume for now that $M > 0$. In this case (3.29) implies

$$E(t) \leq \frac{\epsilon}{2M} Z(0) + \sum_{i=0}^1 \frac{\epsilon_i}{4M} \int_D \frac{1}{S} (b_i)^2 dx dy + \frac{1}{M} \left\{ |H_*(t)| + \left[\left(\frac{1}{\epsilon_0} + \frac{1}{\epsilon_1} \right) \frac{F(\chi)}{4} + \frac{1}{4\epsilon} \right] H_{**}(t) \right\}, \quad (3.31)$$

which together with (3.10) and (3.11) yields

$$\begin{aligned} \left(c_0 - \frac{\epsilon_0}{2M} \right) \int_D \frac{1}{S} (b_0)^2 dx dy + \left(c_1 - \frac{\epsilon_1}{2M} \right) \int_D \frac{1}{S} (b_1)^2 dx dy \leq \frac{\epsilon}{M} Z(0) + \frac{2}{M} |H_*(t)| \\ + \frac{2}{M} \left[\left(\frac{1}{\epsilon_0} + \frac{1}{\epsilon_1} \right) \frac{F(\chi)}{4} + \frac{1}{4\epsilon} \right] H_{**}(t) + 2(E(0) + |A(0)| + |H_1(0)| + |H_1(t)|). \end{aligned} \quad (3.32)$$

This last result provides the bound that we need to prove nonlinear stability. Specifically, if there exist positive constants ϵ_0 , ϵ_1 , ϵ , and χ such that $M > 0$ and the coefficients of the two integrals on the left-hand side of (3.32) are both positive, then (3.32) provides an upper bound for $E_b(t)$. This bound together with (3.31) provides an upper bound for $E(t)$. The question then becomes whether these bounds can be expressed in terms of the initial disturbance. To see this, we need to consider the right-hand side of (3.32). First consider $H_1(t)$, which is defined by (3.7): using (2.10) together with the Hölder inequality we have

$$\begin{aligned} |H_1(t)| \leq \left(\int_{\Omega} (\Psi + \alpha y)^2 dx dy dz \right)^{1/2} \\ \times \left(\int_{\Omega} (q_0)^2 dx dy dz \right)^{1/2}, \end{aligned} \quad (3.33)$$

where $q_0 = q(x, y, z, 0)$. In this way $|H_1(t)|$ can be bounded in terms of the initial disturbance field, with the bound tending to zero as the initial disturbance tends to zero. In appendix A, upper bounds on $|H_*(t)|$ and $H_{**}(t)$ are established in terms of the initial disturbance field, which likewise tend to zero uniformly as the initial disturbance tends to zero. The initial quan-

ties $E(0)$, $|A(0)|$, and $|H_1(0)|$ all tend to zero in the limit of the initial disturbance tending to zero. Therefore, whenever constants ϵ_0 , ϵ_1 , ϵ , and χ exist satisfying the above-mentioned conditions, it follows that the Eady basic state is nonlinearly stable in the sense defined in the introduction.

b. Stability criterion

The problem now reduces to determining conditions under which there exist constants ϵ_0 , ϵ_1 , ϵ , and χ such that

$$\epsilon_0 > 0, \quad \epsilon_1 > 0, \quad \epsilon > 0, \quad \chi > 0, \quad M > 0, \\ 2Mc_0 > \epsilon_0, \quad \text{and} \quad 2Mc_1 > \epsilon_1, \quad (3.34)$$

where M is defined by (3.30) and c_i are defined by (3.9). It can be shown that a necessary and sufficient condition for (3.34) to hold is that

$$\lambda_2 - F_1 \left(\frac{1}{c_0} + \frac{1}{c_1} \right) - F_2 \left(\frac{1}{c_0} + \frac{1}{c_1} \right)^2 > 0, \quad (3.35)$$

where $\lambda_2 > 0$ is defined in terms of the eigenvalue problem (3.24), and F_1 and F_2 are positive constants defined by (3.21). That (3.35) implies (3.34) is proved below. The "necessary" part of the statement, that (3.34) implies (3.35), is proved in appendix B.

Thus, suppose that (3.35) holds; if we define $\kappa = (1/c_0) + (1/c_1)$, then (3.35) is equivalent to

$$\lambda_2 \left(\frac{1}{\kappa} \right)^2 - F_1 \left(\frac{1}{\kappa} \right) - F_2 > 0. \quad (3.36)$$

The left-hand side of (3.36) is a quadratic form in $1/\kappa$, with positive and negative roots; since $1/\kappa$ is positive, it is clear that the inequality (3.36) can hold only if $1/\kappa$ is greater than the positive root, namely

$$\frac{F_1 + \sqrt{F_1^2 + 4\lambda_2 F_2}}{2\lambda_2} < \frac{1}{\kappa}.$$

It follows that we may choose χ in the interval

$$\frac{F_1 + \sqrt{F_1^2 + 4\lambda_2 F_2}}{2\lambda_2} < \chi < \frac{1}{\kappa}. \quad (3.37)$$

The left-hand inequality of (3.37) implies

$$\lambda_2 \chi^2 - F_1 \chi - F_2 > 0; \quad (3.38)$$

this may be equivalently written as $\tau < 1$, where $\tau \equiv F(\chi)/(\chi\lambda_2)$, with $F(\chi)$ defined by (3.21). The right-hand inequality of (3.37) implies that $\chi\kappa < 1$, which means that we may choose δ_2 in the interval

$$0 < \frac{1 - \sqrt{1 - \chi\kappa}}{2} < \delta_2 < \frac{1 + \sqrt{1 - \chi\kappa}}{2} < 1. \quad (3.39)$$

Obviously such a δ_2 lies between the two roots of the quadratic $x^2 - x + \chi\kappa/4 = 0$. Therefore,

$$\delta_2^2 - \delta_2 + \frac{\chi\kappa}{4} < 0,$$

which using the definition of κ is equivalent to

$$\frac{\chi}{4c_0(1 - \delta_2)} < \delta_2 - \frac{\chi}{4c_1(1 - \delta_2)}. \quad (3.40)$$

[Note that $\delta_2 < 1$, by (3.39).] In virtue of (3.40), we may choose δ_3 such that

$$\frac{\chi}{4c_0(1 - \delta_2)} < \delta_3 < \delta_2 - \frac{\chi}{4c_1(1 - \delta_2)}. \quad (3.41)$$

Since $0 < \tau < 1$, we may choose δ_1 such that

$$\tau\delta_2 < \delta_1 < \delta_2. \quad (3.42)$$

Finally, let

$$\epsilon = \frac{1}{2\lambda_2(\delta_1 - \tau\delta_2)}, \quad \epsilon_0 = \frac{\chi}{2\delta_3}, \quad \epsilon_1 = \frac{\chi}{2(\delta_2 - \delta_3)}. \quad (3.43)$$

With these choices, it can be seen that $M = \min\{1 - \delta_1, 1 - \delta_2\} = 1 - \delta_2$. It is not difficult to verify that such ϵ , ϵ_0 , ϵ_1 , and χ do indeed satisfy (3.34). Hence (3.35) implies (3.34).

Since the condition (3.35) depends on α , the goal is now to choose α in order to get the sharpest possible form of the criterion (3.35), that is, the one holding for the smallest possible value of λ_2 . It is clear from the form of (3.35) that this is obtained when κ takes its minimum value, which occurs at $\alpha = \Lambda(z_0 + z_1)/2$ and is $\kappa = 4/(z_1 - z_0)$. Note that this value of α lies within the range (3.8), so it is an acceptable choice. Using this value of α , and noting that $\lambda_2 = \pi^2/4Y^2$, (3.35) then implies

$$\frac{\pi}{2Y} > \frac{2\sqrt{5}f}{(z_1 - z_0)N}. \quad (3.44)$$

We may therefore state the following nonlinear stability theorem: If the width of the channel $2Y$ and the vertical height of the domain $(z_1 - z_0)$ satisfy (3.44), then the Eady basic state $U = \Lambda z$ is stable to disturbances of arbitrary form and amplitude. In particular, the potential enstrophy, the energy, and the boundary available potential energy of the disturbances are bounded uniformly in time in terms of the initial disturbance, with such bounds decreasing to zero as the initial disturbance decreases to zero. Note that the condition (3.44) is independent of the basic-state shear Λ .

It is of interest to compare the nonlinear criterion (3.44) with the stability criterion arising in the linear (normal mode) stability theory, which is

$$\frac{\pi}{2Y} > \frac{2.40f}{(z_1 - z_0)N} \quad (3.45)$$

(e.g., Pedlosky 1987). When the condition (3.45) is satisfied, then the Eady basic state is linearly stable to

disturbances of fixed spatial structure (normal modes) having $q \equiv 0$. Conditions (3.44) and (3.45) are clearly quite similar, differing only by a numerical factor, but their theoretical content is very different. The two criteria are, of course, consistent with one another. Whether the different numerical factor represents something fundamental—in the sense of there being a regime wherein the flow is not subject to normal-mode instability yet is nevertheless unstable in a normed sense—is something the authors do not yet understand. It is a subject that deserves further investigation.

4. Discussion

By using exact invariants of the full nonlinear dynamics, a nonlinear stability theorem has been obtained for the Eady basic state $U = \Lambda z$ in the continuously stratified, f -plane, Boussinesq model of quasigeostrophic flow. In particular, when the physical parameters of the problem are such that (3.44) is satisfied, then the basic state is nonlinearly stable to disturbances of arbitrary form and magnitude (possibly having non-zero potential vorticity). What is meant by nonlinear stability in this context is that the important quadratic measures of disturbance amplitude—the potential enstrophy, the energy, and the available potential energy on the rigid lids—are all bounded in terms of the initial disturbance, with the bounds decreasing to zero as the initial disturbance decreases to zero. This definition of stability is to be distinguished from the strict mathematical definition of Liapunov stability, which bounds disturbance norms in terms of the initial values of those same norms.

Although the present result may be regarded as an analogue of Arnol'd's second nonlinear stability theorem for this problem, there are some notable differences. In particular, the key inequality (3.32) bounds a quadratic disturbance quantity by a quantity involving a linear disturbance quantity, H_1 ; this in turn reflects the fact that the conserved functional $H(t)$ has a non-vanishing first variation at the basic state. Both of these features distinguish the present approach from the energy-Casimir stability methodology of Arnol'd (1965, 1966; see also Holm et al. 1985).

Another difference with Arnol'd's second theorem concerns interpretation. Insofar as the stability criterion (3.44) is a geometric condition, one might be tempted to interpret it as a condition on the scale of the basic flow as compared with the scale of dynamically admissible disturbances. It is well known (McIntyre and Shepherd 1987, appendix B) that in the case of homogeneous boundary conditions, Arnol'd's second theorem can be understood in terms of Fjørtoft's (1953) "anticascade" theorem in precisely this way. However, with inhomogeneous boundary conditions such as arise in Eady's model, the "scale" of the disturbance is not a well-defined concept; thus, an interpretation in terms of the anticascade theorem would seem to be

unjustified. This is in contrast to the case of the Phillips model of baroclinic instability, where the analogy with Arnol'd's second theorem is more direct; there the short-wave part of the marginal stability curve coincides precisely with the nonlinear stability threshold (Mu et al. 1994).

The nonlinear stability criterion (3.44) is qualitatively similar to the linear (normal mode) criterion (3.45), differing only by a numerical factor. However, the theoretical content of the two criteria is quite different. Whereas linear stability theorems only delineate parametric regions of possible instability, an important feature of nonlinear stability theorems is that they provide rigorous upper bounds on disturbance norms in terms of the initial conditions of the problem. These bounds may be useful in setting limits on possible non-modal transient growth, for example. And when the initial flow is unstable but sufficiently close to a stable flow—in a sense that may be made mathematically precise—this feature may be used to determine rigorous upper bounds on the saturation amplitude of the unstable disturbance (Shepherd 1988 et seq.). An application of this method to the present problem could provide an interesting complementary theory to Drazin's (1970) weakly nonlinear analysis of baroclinic instability in the Eady model.

APPENDIX A

Upper Bounds on $H_{**}(t)$ and $|H_*(t)|$

a. The estimate for $H_{**}(t)$

From the definition (3.28),

$$H_{**}(t) = \int_{\Omega} \left\{ \frac{1}{\lambda_2} |\nabla \psi_0|^2 + (\psi_0)^2 \right\} dx dy dz + 2(A_1 + A_2), \quad (\text{A.1})$$

where

$$A_1 = \int_{\Omega} |\psi_0(\tilde{\psi} - \psi_0)| dx dy dz,$$

$$\begin{aligned} A_2 &= \int_{\Omega} \frac{1}{\lambda_2} |\nabla \psi_0 \cdot \nabla \tilde{\psi}| dx dy dz \\ &= \int_{\Omega} \frac{1}{\lambda_2} |\nabla \psi_0 \cdot \nabla \psi| dx dy dz. \end{aligned}$$

Using the Hölder and Poincaré inequalities,

$$\begin{aligned}
 A_1 &\leq \left(\int_{\Omega} (\psi_0)^2 dx dy dz \right)^{1/2} \left(\int_{\Omega} (\tilde{\psi} - \psi_0)^2 dx dy dz \right)^{1/2} \\
 &\leq \left(\int_{\Omega} (\psi_0)^2 dx dy dz \right)^{1/2} \frac{1}{\sqrt{\lambda_2}} \\
 &\quad \times \left(\int_{\Omega} |\nabla(\tilde{\psi} - \psi_0)|^2 dx dy dz \right)^{1/2} \\
 &= \frac{1}{\sqrt{\lambda_2}} \left(\int_{\Omega} (\psi_0)^2 dx dy dz \right)^{1/2} \\
 &\quad \times \left(\int_{\Omega} |\nabla(\Psi + \tilde{\psi}) - \nabla(\Psi + \psi_0)|^2 dx dy dz \right)^{1/2} \\
 &\leq \frac{\sqrt{2}}{\sqrt{\lambda_2}} \left(\int_{\Omega} (\psi_0)^2 dx dy dz \right)^{1/2} \left(\int_{\Omega} \{ |\nabla(\Psi + \tilde{\psi})|^2 \right. \\
 &\quad \left. + |\nabla(\Psi + \psi_0)|^2 \} dx dy dz \right)^{1/2}. \quad (\text{A.2})
 \end{aligned}$$

Now using conservation of total energy (2.5), together with the fact that φ does not contribute to the energy, (A.2) implies

$$\begin{aligned}
 A_1 &\leq \frac{\sqrt{2}}{\sqrt{\lambda_2}} \left(\int_{\Omega} (\psi_0)^2 dx dy dz \right)^{1/2} \\
 &\quad \times \left(\int_{\Omega} \left\{ 2|\nabla(\Psi + \psi_0)|^2 \right. \right. \\
 &\quad \left. \left. + \frac{1}{S} [(\Psi + \psi_0)_z]^2 \right\} dx dy dz \right)^{1/2}. \quad (\text{A.3})
 \end{aligned}$$

Using similar manipulations,

$$\begin{aligned}
 A_2 &\leq \frac{1}{\lambda_2} \left(\int_{\Omega} |\nabla \psi_0|^2 dx dy dz \right)^{1/2} \\
 &\quad \times \left(\int_{\Omega} |\nabla \tilde{\psi}|^2 dx dy dz \right)^{1/2} \\
 &\leq \frac{\sqrt{2}}{\lambda_2} \left(\int_{\Omega} |\nabla \psi_0|^2 dx dy dz \right)^{1/2} \\
 &\quad \times \left(\int_{\Omega} \{ |\nabla(\Psi + \psi)|^2 + |\nabla \Psi|^2 \} dx dy dz \right)^{1/2} \\
 &\leq \frac{\sqrt{2}}{\lambda_2} \left(\int_{\Omega} |\nabla \psi_0|^2 dx dy dz \right)^{1/2} \\
 &\quad \times \left(\int_{\Omega} \left\{ |\nabla(\Psi + \psi_0)|^2 + \frac{1}{S} [(\Psi + \psi_0)_z]^2 \right. \right. \\
 &\quad \left. \left. + |\nabla \Psi|^2 \right\} dx dy dz \right)^{1/2}, \quad (\text{A.4})
 \end{aligned}$$

again using conservation of total energy. The combination of (A.1), (A.3), and (A.4) demonstrates that

$H_{**}(t)$ is bounded from above by a quantity depending only on the initial disturbance, which tends to zero as the initial disturbance tends to zero.

b. The estimate for $|H_*(t)|$

From the definition (3.19) together with the Hölder inequality, we have

$$\begin{aligned}
 |H_*(t)| &\leq \frac{1}{2} \left(\int_{z_0}^{z_1} \tilde{\psi}^2 \Big|_{y=Y} dz \right)^{1/2} \\
 &\quad \times \left(\int_{z_0}^{z_1} \left[\int_{-X}^X \frac{\partial \psi_0}{\partial y} dx \Big|_{y=Y} \right]^2 dz \right)^{1/2} \\
 &\quad + \frac{1}{2} \left(\int_{z_0}^{z_1} \tilde{\psi}^2 \Big|_{y=-Y} dz \right)^{1/2} \\
 &\quad \times \left(\int_{z_0}^{z_1} \left[\int_{-X}^X \frac{\partial \psi_0}{\partial y} dx \Big|_{y=-Y} \right]^2 dz \right)^{1/2}. \quad (\text{A.5})
 \end{aligned}$$

The problem now reduces to bounding the integrals of $\tilde{\psi}^2$ in the above expression in terms of the initial disturbance. To this end, let $\gamma(y) \equiv (y + Y)/(2Y)$. First consider $y = Y$:

$$\begin{aligned}
 [\tilde{\psi}(x, Y, z, t)]^2 &= \int_{-Y}^Y \frac{\partial}{\partial y} \{ \gamma(y) \tilde{\psi}^2 \} dy \\
 &= \frac{1}{2Y} \int_{-Y}^Y \tilde{\psi}^2 dy + \int_{-Y}^Y 2\gamma(y) \tilde{\psi} \tilde{\psi}_y dy \\
 &\leq \frac{2Y+1}{2Y} \int_{-Y}^Y \tilde{\psi}^2 dy + \int_{-Y}^Y (\tilde{\psi}_y)^2 dy.
 \end{aligned} \quad (\text{A.6})$$

The left-hand side of (A.6) is independent of x , by the boundary condition (2.4a). Noting this, and integrating (A.6) over x and z , then yields

$$\begin{aligned}
 \int_{z_0}^{z_1} \tilde{\psi}^2 \Big|_{y=Y} dz &\leq \frac{2Y+1}{4XY} \int_{\Omega} \tilde{\psi}^2 dx dy dz \\
 &\quad + \frac{1}{2X} \int_{\Omega} |\nabla \tilde{\psi}|^2 dx dy dz. \quad (\text{A.7})
 \end{aligned}$$

Using (3.27) with (A.7), we then have

$$\begin{aligned}
 \int_{z_0}^{z_1} \tilde{\psi}^2 \Big|_{y=Y} dz &\leq \left(\frac{2Y+1}{4XY\lambda_2} + \frac{1}{2X} \right) \\
 &\quad \times \int_{\Omega} |\nabla \tilde{\psi}|^2 dx dy dz + \frac{2Y+1}{4XY} H_{**}(t) \\
 &\leq \left(\frac{2Y+1}{2XY\lambda_2} + \frac{1}{X} \right) \int_{\Omega} \left\{ |\nabla(\Psi + \psi_0)|^2 \right. \\
 &\quad \left. + \frac{1}{S} [(\Psi + \psi_0)_z]^2 + |\nabla \Psi|^2 \right\} dx dy dz \\
 &\quad + \frac{2Y+1}{4XY} H_{**}(t), \quad (\text{A.8})
 \end{aligned}$$

the last inequality following from conservation of energy, as in (A.4).

Precisely the same manipulations lead to (A.8) with $y = Y$ on the left-hand side replaced by $y = -Y$. Since $H_{**}(t)$ has been shown in section a of this appendix to be bounded in terms of the initial disturbance, the combination of (A.5) with (A.8) demonstrates that $|H_*(t)|$ is bounded from above by a quantity depending only on the initial disturbance, which tends to zero as the initial disturbance tends to zero.

APPENDIX B

Proof That (3.34) Implies (3.35)

We show below that (3.34) implies (3.35)—equivalently, that the latter condition is necessary for the existence of constants ϵ , ϵ_0 , ϵ_1 , and χ satisfying (3.34).

Therefore, suppose that ϵ , ϵ_0 , ϵ_1 , and χ exist satisfying (3.34). Let

$$\delta_1 = \left(\frac{1}{\epsilon_0} + \frac{1}{\epsilon_1} \right) \frac{F(\chi)}{2\lambda_2} + \frac{1}{2\epsilon\lambda_2},$$

$$\delta_2 = \frac{\chi}{2} \left(\frac{1}{\epsilon_0} + \frac{1}{\epsilon_1} \right), \quad \delta_3 = \frac{\chi}{2\epsilon_0}, \quad (\text{B.1})$$

which is equivalent to (3.43). The hypothesis (3.34) implies

$$2Mc_0 > \frac{\chi}{2\delta_3}, \quad 2Mc_1 > \frac{\chi}{2(\delta_2 - \delta_3)},$$

$$0 < \delta_3 < \delta_2 < 1, \quad \tau\delta_2 < \delta_1 < 1, \quad \chi > 0, \quad (\text{B.2})$$

where $M = \min\{1 - \delta_1, 1 - \delta_2\}$.

There are two cases to consider. In the case $\delta_1 \geq \delta_2$, we have $M = 1 - \delta_1$, and (B.2) thus implies

$$2c_0(1 - \delta_1) > \frac{\chi}{2\delta_3}, \quad 2c_1(1 - \delta_1) > \frac{\chi}{2(\delta_2 - \delta_3)}.$$

Hence,

$$\frac{\chi}{4c_0(1 - \delta_1)} < \delta_3 < \delta_2 - \frac{\chi}{4c_1(1 - \delta_1)}$$

$$< \frac{\delta_1}{\tau} - \frac{\chi}{4c_1(1 - \delta_1)}. \quad (\text{B.3})$$

The inequality obtained by omitting the two middle terms of (B.3) is equivalent to

$$\delta_1^2 - \delta_1 + \frac{\chi\kappa\tau}{4} < 0, \quad (\text{B.4})$$

recalling the definition $\kappa = (1/c_0) + (1/c_1)$. Since $\delta_1 > 0$ satisfies the inequality (B.4), the quadratic must have real roots; this implies

$$1 - \chi\kappa\tau > 0, \quad (\text{B.5})$$

which is equivalent to

$$\lambda_2 - F_1\kappa - \frac{F_2\kappa}{\chi} > 0 \quad (\text{B.6})$$

since $\tau = F(\chi)/(\chi\lambda_2)$. On the other hand, (B.3) and the fact that $\delta_2 \leq \delta_1$ yields

$$\frac{\chi}{4c_0(1 - \delta_1)} < \delta_3 < \delta_1 - \frac{\chi}{4c_1(1 - \delta_1)}.$$

Omitting the middle part of the above inequality produces

$$\delta_1^2 - \delta_1 + \frac{\chi\kappa}{4} < 0. \quad (\text{B.7})$$

Since $\delta_1 > 0$ satisfies (B.7), an analogous argument to that concerning (B.4) implies

$$1 - \chi\kappa > 0 \Leftrightarrow \kappa < \frac{1}{\chi}. \quad (\text{B.8})$$

Combining (B.8) with (B.6) then implies

$$\lambda_2 - F_1\kappa - F_2\kappa^2 > 0, \quad (\text{B.9})$$

which is just (3.35).

The second case to consider is $\delta_1 < \delta_2$, for which $M = 1 - \delta_2$ and (B.2) therefore implies

$$2c_0(1 - \delta_2) > \frac{\chi}{2\delta_3}, \quad 2c_1(1 - \delta_2) > \frac{\chi}{2(\delta_2 - \delta_3)}.$$

Hence,

$$\frac{\chi}{4c_0(1 - \delta_2)} < \delta_3 < \delta_2 - \frac{\chi}{4c_1(1 - \delta_2)},$$

which implies that

$$\delta_2^2 - \delta_2 + \frac{\chi\kappa}{4} < 0. \quad (\text{B.10})$$

The fact that $\delta_2 > 0$ satisfies (B.10) then implies (B.8). In this case, since $\tau\delta_2 < \delta_1 < \delta_2$, it follows that $0 < \tau < 1$, which is equivalent to

$$\chi > \frac{F_1 + \sqrt{F_1^2 + 4\lambda_2 F_2}}{2\lambda_2}. \quad (\text{B.11})$$

Combining (B.11) with (B.8) then implies (B.9), which is just (3.35).
