Abstract

Despite the fact that physical health and cognitive abilities decline with aging, the ability to regulate emotion remains stable and in some aspects improves across the adult life span. Older adults also show a positivity effect in their attention and memory, with diminished processing of negative stimuli relative to positive stimuli compared with younger adults. The current paper reviews functional magnetic resonance imaging studies investigating age-related differences in emotional processing and discusses how this evidence relates to two opposing theoretical accounts of older adults' positivity effect. The aging-brain model [1] proposes that older adults' positivity effect is a consequence of age-related decline in the amygdala, whereas the cognitive control hypothesis [2-4] argues that the positivity effect is a result of older adults' greater focus on regulating emotion. Based on evidence for structural and functional preservation of the amygdala in older adults and findings that older adults show greater prefrontal cortex activity than younger adults while engaging in emotion processing tasks, we argue that the cognitive control hypothesis is a more likely explanation for older adults' positivity effect than the aging-brain model.

Keywords: emotion, aging, functional magnetic resonance imaging, positivity effect, amygdala, prefrontal cortex

In contrast with the age-related declines in many domains of cognitive functioning [5], emotion regulation functioning improves somewhat with age [6]. People experience less negative affect as they get older and can restore their good mood after induced into a negative mood more effectively than younger adults [2]. Older adults also show a “positivity effect” in attention and memory [3]. For instance, older adults sometimes spend a larger proportion of time viewing positive items and a smaller proportion viewing negative items than do younger adults [7,8]. Moreover, in some studies, compared with younger adults, less of what older adults remember is negative and more is positive [4,7,9]. Such age by valence interactions tend to have a medium effect size [9]; thus, as might be expected, studies with relatively small participant groups do not always reveal significant age differences. Other factors, such as a level of arousal of stimuli [10], availability of cognitive resources [8] or types of measurements across studies [11], may also account for the presence or absence of a positivity effect.

Why do older adults show some improvements in emotion regulation despite suffering age-related cognitive decline? One possibility is that age-related decline in brain regions that monitor negative, potentially threatening information reduces negative affect. This is the argument made by Cacioppo et al.’s aging-brain model [1], which proposes that age-related decline in the amygdala leads to the positivity effect. This argument is based on the observation that patients with amygdala lesions are worse at rating the arousal or intensity of negative stimuli, but not of positive stimuli [12,13]. Cacioppo et al. propose that age-related decline in the amygdala selectively diminishes emotional arousal in response to negative stimuli (but not positive stimuli) and, as a result, older adults fail to get the memorial advantage of high arousal associated with negative stimuli and experience less negative affect.

A different possibility is that age-related diminishment of negative affect occurs because older adults are more focused on regulating emotion in their everyday lives. Previous research suggests that older adults are more likely than younger adults to prioritize emotion regulatory goals over other goals [14], and to regulate emotion when induced into a negative mood [15]. Effective emotion regulation requires self-directed attention and memory – for instance, attention should avoid negative information that could impair one’s mood and memory processes should be directed to increase the prevalence of positive, mood-enhancing thoughts. Being guided by emotion regulation goals rather than by currently salient stimuli requires the types of cognitive control processes implemented by the prefrontal cortex (PFC)[16]. Based on this line of reasoning, the cognitive control model [2-4] argues that older adults’ positivity effect is due to their greater focus on regulating emotions and requires cognitive control processes. This idea is consistent with behavioral evidence suggesting that the positivity effect emerges especially when older adults have enough cognitive resources, and when this effort is not readily available, they show no positivity effect [8,17,18]. Furthermore, the positivity effect is most robust for items low in arousal, as low arousing items are more likely to engage cognitive control processes whereas high arousing items require relatively automatic processes [10].

In this paper, we review recent functional magnetic resonance imaging (fMRI) studies of age differences in emotional processing and discuss how they relate to these two opposing theoretical accounts of older adults’ positivity effect. The aging-brain and cognitive-control models make different predictions about how aging should affect brain activity during emotion processing. The aging-brain model argues that age-related functional decline in the amygdala causes the positivity effect, whereas the cognitive control model assumes that prefrontal regulation of emotional processing causes the positivity effect.

Structural Preservation of the Amygdala in Aging

Imaging studies indicate that there is less volumetric decline with age in the amygdala than in most other brain regions [19,20] and post-mortem measurements based on histological staining reveal no significant effect of age on amygdala volume [21]. Thus, contrary to the aging-brain model, older adults do not appear to suffer from focal damage in the amygdala and patients with amygdala damage are unlikely to be a useful neuropsychological model of the effects of aging.

Consistent with the structural preservation of the amygdala, emotional processing is well preserved in normal aging. Previous research suggests that the ability to detect emotionally arousing stimuli is relatively stable with age [22], and that the effects of emotional arousal on memory remain intact in normal aging [23]. Furthermore, younger and older adults produce similar skin conductance responses to emotionally arousing stimuli [23,24].

Functional Neuroimaging Comparisons of Younger and Older Adults' Amygdala Activity

Despite structural preservation of the amygdala in normal aging, fMRI studies have revealed some age differences in amygdala activity. The difference seen most consistently across studies is an age-related decrease in activation in response to negative stimuli [25-28]. This decrease in amygdala activity in response to negative stimuli is predicted by both theoretical perspectives. The aging-brain model predicts that age-related amygdala decline reduces amygdala responsivity to emotionally arousing stimuli. In contrast, the cognitive-control model predicts that prefrontal emotion regulation processes diminish amygdala responses to negative, but not positive stimuli—thus, age-related decreases in amygdala activity when viewing negative stimuli are not due to inherent amygdala impairments. Although both explanations are plausible,

prior studies provide more evidence for the cognitive control model. Below, we first describe results consistent with the cognitive control model, followed by results contradicting the aging-brain model's assumptions.

In line with the cognitive-control model, past studies revealed a link between diminished amygdala activity to negative stimuli and emotion regulation skills. In one study, for participants between 30 and 54 years old but not for younger adults, reduced amygdala activity to negative stimuli was associated with a trait tendency to use an effective emotion regulation strategy (i.e., reappraisal) [25]. That is, higher reappraisal tendency predicted lower amygdala activation during viewing negative stimuli than during neutral ones. Furthermore, in another study, older adults who showed lower amygdala signal to negative stimuli showed more effective regulation of diurnal cortisol levels in the week following the scan [29]. Although these are correlational results, they suggest that older adults' reduced amygdala response to negative stimuli does not reflect impaired amygdala function, but instead emotion regulation efforts.

Furthermore, research on Alzheimer's disease (AD) provides a counterpoint to the aging-brain model's assumption that decreased amygdala activity is a sign of age-related decline in the amygdala. The amygdala is one of the brain regions typically most affected by Alzheimer's disease [29,30]. A study comparing amygdala responses in younger, older, and AD patients while viewing familiar neutral and novel fearful human faces revealed that the AD group showed significantly greater amygdala responses to both types of faces relative to elderly controls [31]. Importantly, greater hyperactivity was associated with greater severity of irritability and agitation symptoms in AD. The results suggest that disease-related amygdala decline leads to hyperactive amygdala responses, and therefore that reduced amygdala response to negative stimuli seen among healthy older adults is not a symptom of early AD.

In addition, contrary to the aging-brain model's assumption that the amygdala declines with age, there is evidence that the amygdala's function is preserved in healthy older adults [32]. First, in two studies that included both positive and negative pictures, age-related decreases in amygdala activity were seen for negative but not positive pictures [25,26]. Thus, even in older adults who showed reduced amygdala activity to negative stimuli, their amygdala can be still activated by a certain type of emotional stimuli. Second, the amygdala in older adults is sometimes activated even by negative stimuli. In one study [33], for example, both younger and older adults showed enhanced amygdala activity to negative compared to neutral photographs. Importantly, the amygdala activation in older adults involved overlapping areas with younger adults, suggesting that older adults depend on the same amygdala regions to process negative stimuli as younger adults. Furthermore, research on emotional memory demonstrated that the amygdala plays an important role in enhancing memory for emotional stimuli both in younger and older adults [34-36]. Taken together, these findings suggest that the amygdala functions similarly in healthy older adults as it does in younger adults. Thus, it seems unlikely that the reduced amygdala activity to negative stimuli in older adults is caused by age-related impairment of the amygdala as the aging-brain model predicts.

Age-related Differences in Prefrontal Cortex Activity during Emotion Processing

While the cognitive-control and aging-brain models both predict reduced amygdala activity to negative stimuli in older adults, the two models make different predictions about PFC activity during emotion processing. In contrast to the aging-brain model, which makes no specific predictions about PFC responsivity to emotional stimuli, the cognitive control model argues that if older adults' positivity effects are the result of a greater focus on emotion regulation goals, older adults should recruit more PFC while encountering emotional stimuli than

do younger adults, because the PFC is involved in cognitive control of emotion [16,29,37].

Importantly, such age-related increases in PFC activity should exceed those seen in response to neutral stimuli. Increases in PFC activity are expected for down-regulation of negative emotion (i.e., dampening of emotional responses or attentional avoidance of negative stimuli) and for up-regulation of positive emotion (i.e., enhancing emotional responses to positive stimuli). To address these predictions, we review prior studies examining age differences in PFC activity in response to negative and positive stimuli (although there are fewer studies with positive stimuli; further investigation is needed).

Greater PFC activity to negative stimuli in older adults.

Consistent with the prediction made by the cognitive control model, a number of studies report that older adults recruited PFC more for negative than for neutral stimuli compared with younger adults (Figure 1; Table 1). In one study [38], brain activity was measured by fMRI while younger and older adults made indoor-outdoor judgments (i.e., encoding session) and old-new recognition judgments about negative or neutral photographs (i.e., recognition session). The results indicated that older adults recruited dorsolateral PFC more strongly for negative photographs (than for neutral ones) compared with younger adults in the encoding session. Similar patterns were observed in the recognition session; older adults showed increased dorsolateral PFC activity to negative pictures together with reduced amygdala activity compared with younger adults. Other studies also reveal that older adults show increased PFC or anterior cingulate (ACC) activity together with decreased amygdala activity while viewing negative stimuli [27,28]. In addition, relative to younger adults, older adults showed more negative functional connectivity between the right amygdala and ACC while rating emotional pictures [33]. Moreover, the negative correlation between these two regions was observed when older

adults rated negative pictures as neutral, but not when they rated negative pictures as negative. These results are consistent with the cognitive control model, suggesting that PFC/ACC dampened activity in the amygdala while viewing negative stimuli, and that the enhanced PFC activity seen in older adults reflects their efforts to down-regulate negative emotions.

Indeed, the PFC regions activated by older adults in these studies (and in others; see Table 1) are similar to regions implicated in emotion regulation. For instance, Brodmann area (BA) 9 was also activated while people were told to down-regulate their negative emotions to aversive stimuli [37,39]. Likewise, BA 6, 8, 10, 44 and 45 overlap with areas associated with down-regulation of negative emotion [37]. While most emotion regulation findings are based on younger adults, a recent study found that cognitive reappraisal activated similar PFC regions to those mentioned above in both younger and older adults [40]. In addition, there is evidence of negative relationships between the amygdala and PFC during successful emotion regulation [41,42], which is also consistent with the negative amygdala-PFC correlations seen in older adults when they encounter negative stimuli [33]. Taken together, these studies suggest that the enhanced PFC activity to negative stimuli coupled with decreased amygdala activity while encountering negative stimuli may reflect older adults' attempts to regulate their emotions.

Greater PFC activity to positive vs. negative stimuli in older adults.

In addition to increased PFC when processing negative stimuli, older adults sometimes recruited PFC more for positive than negative stimuli (relative to younger adults; see Table 2 and Figure 2). Older adults' increased PFC activity to positive stimuli has been observed when a task requires more elaborative processing of emotional stimuli, rather than passive viewing (such as self-relevant processing [43], semantic judgments [44] or mental manipulation of the perceptual stimulus representation [45]). This may suggest that, when prompted to deeply

process stimuli, older adults engage more with positive than negative stimuli. This idea is supported by two studies examining how the depth of encoding affects brain activity in younger and older adults.

In Ritchey et al. [44], younger and older adults viewed positive, negative or neutral photographs, and either analyzed each picture for its semantic meanings (i.e., semantic elaboration condition), or focused on the colors and lines in the pictures (i.e., shallow condition). In older adults, positive stimuli induced greater activity in medial/superior PFC and inferior PFC under the semantic elaboration condition, but not under the shallow condition. In contrast, in younger adults, these PFC clusters showed similar levels of activity to positive stimuli regardless of the condition. Similar results were observed in another study [43]; compared with younger adults, older adults recruited medial and middle PFC more for positive items relative to negative items when they made self-referential judgments about those stimuli (relative to other-referential judgments). Both semantic elaboration and self-referential processing are known to induce deep processing, requiring cognitive effort [46]. Thus, it appears that older adults recruit PFC for positive stimuli especially when they process those stimuli deeply.

According to the cognitive control model, older adults' greater PFC activity for positive stimuli described above is a result of their effort to up-regulate emotion to experience more positive affect. If this is the case, older adults' brain regions activated while processing positive stimuli should also activate when people up-regulate or try to amplify their positive emotions. Although most emotion regulation studies focused on down-regulation of negative affect, one study [47] used positive and negative stimuli in order to identify regions critical for up-regulation of positive emotions. The identified regions include the dorsomedial PFC (BA 6), the left PFC (BA 8), the medial PFC (BA 10), the medial orbitofrontal cortex (BA 11), and left orbitofrontal

cortex (BA 47). Importantly, these regions are similar to those activated more for positive than negative stimuli while older adults were deeply engaged with these stimuli (BA 8, 10, 11, 47 shown in Table 2). This provides further support for the cognitive control model, suggesting that older adults tend to recruit PFC when encountering positive stimuli in order to feel more positive.

Questions for future research.

While many studies reported enhanced PFC activity to emotional stimuli in older than younger adults (as reviewed above), a few studies reported decreased PFC activity to positive stimuli [25,48] and to negative stimuli in older adults compared to younger adults [25,49]. Some of these age-related reductions in PFC activity during emotion processing may be related to the stimuli presentation sequences used. For instance, in one such study [25], participants were given symbolic cues that informed them about the valence of the subsequent picture. Being able to anticipate negative emotional stimuli may have allowed older adults to engage in antecedent-focused regulation (strategies to regulate emotion before the emotional response has already been fully activated [50]) rather than response-focused regulation that requires more cognitive control. In another study [49], participants viewed blocks of 40 pictures of the same valence for 80 seconds. Overall, older adults had reduced amygdala activity compared with younger adults, especially while viewing the negative pictures. Older adults also showed more PFC activity than younger adults during the first 20 negative pictures but then this greater prefrontal activity habituated by the second half of the blocks. Younger adults did not show this pattern of habituation for any emotional valence and older adults only showed it for the negative pictures. It is possible that, during the 80-s long blocks of negative pictures, older participants initially had emotional responses to each picture and then attempted to down-regulate these emotional responses. As the series of negative pictures continued, however, they may have switched to less

taxing antecedent-focused strategies in which they attempted to avoid having a response to the pictures in the first place. Further research is needed to investigate the role of anticipation of negative affect and how it might affect older adults' PFC engagement while processing negative stimuli.

Summary and Future Directions

This paper compares two theoretical accounts for older adults' positivity effect. The aging-brain model proposes that age-related decline in amygdala activation in response to negative stimuli causes an age-related positivity bias in cognition. In contrast, the cognitive control model argues that older adults' motivational changes direct cognitive control processes to regulate emotion, leading to a positivity effect. Arguing against the aging-brain model, previous neuroimaging evidence suggests that the amygdala remains structurally intact and functionally responsive to various types of stimuli including negatively valenced items. Furthermore, although participants were not instructed to regulate negative or positive emotions explicitly in most studies cited in this paper, older adults showed enhanced PFC activity during emotion processing tasks (relative to neutral conditions) compared with younger adults. These observations are consistent with the possibility that emotion regulation goals are more chronically active for older adults than for younger adults [3,4]. This idea is further supported by the overlap in brain regions activated during emotion processing (with no instructions to regulate emotions induced by emotional stimuli) and during emotion regulation (with specific instructions to regulate emotion).

Future research should investigate age differences in brain activity during spontaneous vs. strategic emotion regulation (especially up-regulation of positive emotion, which has not been well investigated); this would elucidate how much of older adults' emotion regulation

mechanism is chronically activated and how much of it is intentional, and how these underlying mechanisms affect their mood and cognition in general.

	IAPS pictures (negative or neutral)	Recognition task	[Negative > Neutral]	OA > YA	24	6	4	36
Tessitore et al. (2005)	Faces (fear or angry) or geometric shapes	Facial expression matching task or sensorimotor task	[Negative - Neutral]	OA > YA	9	-36	15	22
				OA > YA	44/45	32	15	22
				OA > YA	8	-10	31	40
St.Jacques et al. (2009)	IAPS pictures (negative or neutral)	Valence rating	[Negative R-Negative F] > [Neutral R-Neutral F]	OA > YA	9	-43	27	36
St. Jacquest et al. (2010)	IAPS pictures (negative or neutral)	Valence rating	[Negative > Neutral]	OA > YA	6	33	0	57
				OA > YA	9	2	28	39
Fischer, Nyberg, & Backman (2010)	Faces (fearful or neutral)	Fear or neutral judgment	[Negative R - Negative F] > [Neutral R - Neutral F]	OA > YA	9	23	36	35
Gunning-Dixon et al. (2003)	Faces (happy, sad, anger, fear, or disgust)	Emotion discrimination or age discrimination	[Emotion - age discrimination]	OA > YA	47	-42	22	-5
				OA > YA	10/46	-31	48	12

Erk, Walter, & Abler (2008)	Cues predicting IAPS pictures (negative, positive, or neutral)	Anticipating a picture corresponding to the valence of the cue	[Negative > Neutral]	YA > OA	32	-4	42	0
	IAPS pictures (positive, negative, or neutral)	Passively viewing	[Negative > Neutral]	YA > OA	46	52	22	20
Williams et al. (2006)	Faces (fear, happy, or neutral)	Passively viewing	[Negative > Neutral]	YA > OA	8	-18	25	42
				YA > OA	8	6	40	44
St.Jacques et al. (2009)	IAPS pictures (negative or neutral)	Valence rating	[Negative R-Negative F] > [Neutral R-Neutral F]	YA > OA	6	-26	-6	44
				YA > OA	9	-15	31	30
				YA > OA	6	9	16	52
				YA > OA	6	12	-11	57

R = remembered, F = forgotten, YA = younger adults, OA = older adults, BA = Brodmann area.
Coordinates are in MNI space and plotted in Figure 1.

Table 2. Summary of neuroimaging studies showing age-related differences in prefrontal cortex activity to positive vs. negative or neutral stimuli

Study	Stimulus	Task	Contrast	Age effects	BA	x	y	z
Addis, Leclerc, Muscatell, & Kensinger (2009)	Photo objects (positive, negative, or neutral)	Size judgments	[Positive > Negative]	OA > YA	10/32	-1	35	3
				OA > YA	10/11/47	-34	40	0
Kensinger & Schacter (2008)	Photo objects (positive, negative, or neutral)	Size judgments during encoding and recognition test	[Positive R > Positive F]- [Negative or Neutral R > Negative or Neutral F]	OA > YA	10	-1	30	-2
				OA > YA	24	-8	22	15
				OA > YA	33	8	6	28
Leclerc & Kensinger (2008)	Photo objects (positive, negative, or neutral)	Size judgments	[Positive > Negative]	OA > YA	8	-36	24	48
				OA > YA	32	0	40	-4
				OA > YA	32	12	48	8
				OA > YA	32	17	32	18
Ritchey, Bessette-Symons, Hayes, & Cabeza (in press)	IAPS pictures (positive, negative, or neutral)	Semantic elaboration or Color processing	Age X Task X Valence masked with [Positive > Negative in OA] X [Deep > Shallow in OA]	OA > YA	32	17	32	18
				OA > YA	10	-8	38	19
				OA > YA	10	-22	49	9
				OA > YA	10	20	49	4
				OA > YA	45	-39	15	14
Gutchess, Kensinger, & Schacter (2007)	Positive and negative adjectives	Self, other (Einstein) or case judgments	[Self positive - other positive] > [Self negative - other negative]	OA > YA	8	-28	12	54
				OA > YA	45	50	46	6

Erk, Walter, & Abler (2008)	IAPS pictures (positive, negative, or neutral)	Passively viewing	[Positive > Neutral]	OA > YA	32	12	38	40
				YA > OA	9	-2	64	20
Williams et al. (2006)	Feces (fear, happy, neutral)	Passively viewing	[Positive > Neutral]	YA > OA	6	-18	22	54
				YA > OA	10	20	54	-2

R = remembered, F = forgotten, YA = younger adults, OA = older adults, BA = Brodmann area.

Coordinates are in MNI space and plotted in Figure 2.

Figure 1. Age differences in PFC involvement while processing negative stimuli. Negative stimuli induced greater PFC activity compared with neutral stimuli in older adults than in younger adults (represented by red dots). In some studies, where participants could anticipate negative stimuli, older adults showed less PFC activity than did younger adults (represented by blue dots). See Table 1 for a list of coordinates and studies used in the figure.

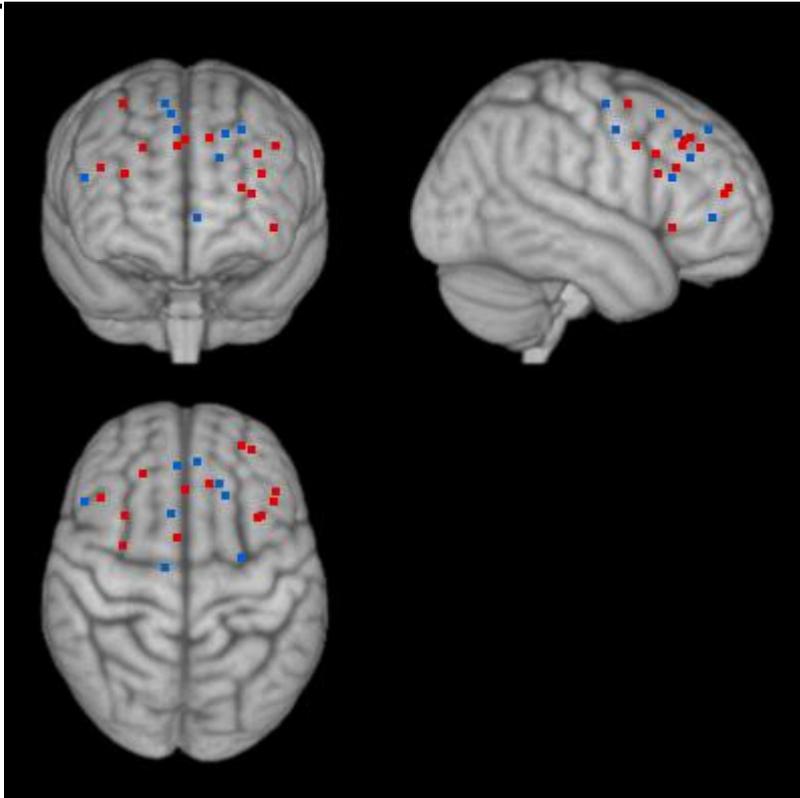

Figure 2. Age differences in PFC involvement while processing positive stimuli. Although some studies showed greater PFC activity to positive stimuli than to neutral stimuli in younger adults than in older adults (shown by blue dots), in studies with tasks requiring deep processing of stimuli, older adults recruited PFC more for positive stimuli than for negative stimuli (relative to younger adults), which is shown by red dots. See Table 2 for a list of coordinates and studies used in the figure.
