Sparse Density Estimation on the Multinomial Manifold
Xia Hong, Junbin Gao, Sheng Chen, and Tanveer Zia

Abstract—A new sparse kernel density estimator is introduced based on the minimum integrated square error criterion for the finite mixture model. Since the constraint on the mixing coefficients of the finite mixture model is on the multinomial manifold, we use the well-known Riemannian trust-region (RTR) algorithm for solving this problem. The first- and second-order Riemannian geometry of the multinomial manifold are derived and utilized in the RTR algorithm. Numerical examples are employed to demonstrate that the proposed approach is effective in constructing sparse kernel density estimators with an accuracy competitive with those of existing kernel density estimators.

Index Terms—Minimum integrated square error (MISE), multinomial manifold, probability density function (pdf), sparse modeling.

I. INTRODUCTION
The probability density function (pdf) estimation problem is fundamental to many data analysis and pattern recognition applications [1]–[6]. The identification of the finite mixture model is usually based on the expectation-maximization (EM) algorithm [7], which provides the maximum likelihood (ML) estimator of the mixture model’s parameters, while the number of mixtures is preset. This associated ML optimization is generally a highly nonlinear optimization process requiring extensive computation. While the EM algorithm for Gaussian mixture model enjoys an explicit iterative form [8], it is also known that this EM algorithm-based ML estimation has a low convergence speed. To tackle the associated numerical difficulties, it is often required to apply resampling techniques [9], [10]. Alternatively, the Parzen window (PW) estimator [11] can be regarded as a special case of the finite mixture model [1], in which the number of mixtures is equal to that of the training data samples and all the mixing weights are equal. The point density estimate using the PW estimator for a future data sample can be computationally expensive if the number of training data samples is very large.

There is a considerable interest in research on sparse pdf estimation. The support vector machine (SVM) density estimation technique has been proposed in [12] and [13]. The optimization in the SVM method is to solve a constrained quadratic optimization problem. This yields the sparsity-inducing property, i.e., at the optimality, many kernels’ weights are driven to zeros. Alternatively, a novel regression-based pdf estimation method has been introduced [14], in which the empirical cumulative distribution function (cdf) is constructed, in the same manner as in the SVM density estimation approach, to be used as the desired response. The orthogonal forward regression (OFR) approach is an efficient supervised regression model construction method [15]. The OFR method has been combined with a leave-one-out test score and local regularization [16], [17]. The regression-based idea of [14] and the approach in [16] and [17] have been extended to yield a new OFR-based sparse density estimation algorithm [18] with a performance comparable with that of the PW estimator. In [14] and [18], the regressors are the cdfs of the kernels and the target response is the empirical cdf. A simple and viable alternative approach has been proposed to use kernels directly as regressors by adopting the PW estimator as the target response [19].

The desirable property of sparsity inducing also happens in the interesting approach of reduced set density estimator (RSDE) [20], based on the minimization of the integrated square error between the estimator and the true density [2], [20], [21] and they introduced two efficient optimization algorithms. Our extensive experience has shown that all the sparse density estimators [12], [13], [18]–[20] discussed here are capable of automatically producing sparse pdf estimates with a performance comparable with that of the PW estimator, but the density estimators of [18]–[20] produce much sparser estimates than the SVM-based density estimator. Recently, a new sparse kernel density estimator has been introduced for sparse kernel density estimation with very low computational cost, based on the MISE and the forward constrained regression (FCR) [22]. In [23] a recursive algorithm, referred to as the FCR-MISE algorithm, has been proposed for the selection of significant kernels one at a time using the minimum integrated square error (MISE) criterion for both kernel selection and the estimation of mixing weights.

Recent years have witnessed great development in Riemannian optimization algorithms on many types of matrix manifolds, such as the Stiefel manifold, Grassmann manifold, and the manifold of positive definite matrices [24, Sec. 3.4]. Since Riemannian optimization is directly based on the curved manifolds, one can eliminate those constraints such as orthogonality to obtain an unconstrained optimization problem that, by construction, will use only feasible points. This allows one to incorporate Riemannian geometry in the resulting optimization problems, thus producing far more accurate numerical results. The recent successful applications of Riemannian optimization in machine learning, computer vision, and data mining, citing a few, include fixed low-rank optimization [25], Riemannian dictionary learning [26], and computer vision tasks [27].

Against this background, this brief introduces a new sparse kernel density estimator based on the MISE criterion for the finite mixture model. Recognizing that the constraint on the mixing coefficients of the finite mixture model is the multinomial manifold, the well-known Riemannian trust-region (RTR) algorithm can be readily used for solving this problem. Clearly, the first- and second-order Riemannian geometry of the multinomial manifold is required and this is developed in this contribution. The proposed algorithm is referred to as the RTR-MISE algorithm. Numerical examples are employed to demonstrate that RTR-MISE is effective in constructing sparse kernel density estimators with an accuracy competitive with those of existing kernel density estimators.

II. SPARSE DENSITY ESTIMATION USING MINIMAL INTEGRATED SQUARE ERROR

Given a finite data set \( D_N = \{x_j\}_{j=1}^N \) consisting of \( N \) data samples, where the data vector \( x_j \in \mathbb{R}^m \) follows an unknown pdf \( p(x) \), the problem under study is to find a sparse approximation of \( p(x) \) based on \( D_N \). A general kernel-based density estimator of \( p(x) \) is given by

\[
\hat{p}(x; \beta, \rho) = \sum_{j=1}^{N} \beta_j K_\rho(x, x_j)
\]

s.t. \( \beta_j \geq 0, \ 1 \leq j \leq N, \) and \( \beta^T 1 = 1 \) \( (2) \)

where \( \beta_j \)'s are the kernel weights, \( \beta = [\beta_1, \beta_2, \ldots, \beta_N]^T \), and \( 1 \) is the vector whose elements are all equal to one, while \( K_\rho(x, x_j) \) is a chosen kernel function with the kernel centre vector \( x_j \) and a suitable kernel width \( \rho \). In this brief, we use the Gaussian kernel of

\[
K_\rho(x, x_j) = \frac{1}{(2\pi \rho^2)^{m/2}} \exp \left(-\frac{||x - x_j||^2}{2\rho^2}\right) \quad (3)
\]

but many other kernels can also be used. The well-known PW estimator, denoted by \( \hat{p}^{PW}(x) \), is a special case of (1) with \( \beta_j = (1/N), \forall j \).

The log-likelihood for \( \beta \) can be formed using observed data \( D_N \), denoted by \( \log L \), as

\[
\log L = \frac{1}{N} \sum_{i=1}^{N} \log \hat{p}(x_i; \beta, \rho) = \frac{1}{N} \sum_{i=1}^{N} \log \left( \sum_{j=1}^{N} \beta_j K_\rho(x_i, x_j) \right) \quad (4)
\]

Note that by the law of large numbers, the log-likelihood of (4) tends to

\[
\int_{\mathbb{R}^m} p(x) \log \hat{p}(x; \beta, \rho) dx \quad (5)
\]

as \( N \to \infty \) with probability one. Equation (4) is simply the negative cross-entropy or divergence between the true density \( p(x) \) and the estimator \( \hat{p}(x; \beta, \rho) \). It can be shown that the PW estimator \( \hat{p}^{PW}(x_j) = (1/N), \forall j \) can be obtained as an optimal estimator via the maximization of (4) with respective to \( \beta \) subject to the constraints \( \beta_j \geq 0, \ 1 \leq j \leq N, \beta^T 1 = 1 \).

The MISE between a pdf estimator and the true density is a classical goodness of fit criterion of probability density estimation, both for nonparametric [2], [20] and for parametric models [21]. The argument \( \hat{\beta} \) which provides the MISE given as

\[
\hat{\beta} = \text{argmin}_{\beta} \left\{ \sum_{i=1}^{N} \left( \sum_{j=1}^{N} \beta_j \beta_i \int K_\rho(x, x_i)K_\rho(x, x_j) dx \right) \right. \\
- \sum_{i=1}^{N} \beta_j E[K_\rho(x, x_j)] \left. \right\} \quad (7)
\]

where \( Q = \{q_{ij}\} \in \mathbb{R}^{N \times N} \) is a matrix with its elements \( q_{ij} \) as \( K_\rho(x_i, x_j) \) and \( p = [\hat{p}^{Par}(x_1), \ldots, \hat{p}^{Par}(x_N)]^T \in \mathbb{R}^{N \times 1} \) is a vector with the elements of \( \hat{p}^{Par}(x_j) = (1/N) \sum_{i=1}^{N} K_\rho(x_i, x_j) \), which is the Parzen pdf estimation for point \( x_j \) using kernel \( 3 \). Note that in (7), the identity \( \int K_\rho(x, x_i)K_\rho(x, x_j) dx = K_\rho(x_i, x_j) \) was applied.

As discussed in [2] and [20], the above MISE estimator over the constraint (2) will end up setting many \( \beta_j \)'s associated with low density \( \hat{p}^{Par}(x_j) \) as zeros. However, the resultant estimator may still not be very sparse. In linear-in-the-parameters modeling and kernel methods, the number of terms in the model is referred as the 0-norm of the parameter vector. Minimizing such quantity is related to variable and feature selection, ensuring model sparsity and generalization [28]. Because of the intractability in the minimization of the 0-norm, there is considerable research on the approximation schemes on the 1-norm [28] and the associated computational complexities. It was analyzed that when combined with the convexity constraint of the kernel parameter vector, model sparsity can be achieved by maximizing of the 1-norm of the parameters [29]. Thus, our optimization problem is given as

\[
\min_{\beta \in \mathbb{R}^N} \left\{ F(\beta) = \frac{1}{2} \beta^T C \beta - \beta^T p \right\} \quad (8)
\]

s.t. \( \beta_j \geq 0, \ 1 \leq j \leq N, \) and \( \beta^T 1 = 1 \) \( (9) \)

where \( C = Q - \delta I \), \( I \) is the identity matrix. \( \delta \) is zero or a very small preset positive number that directly controls the sparsity. The larger the value \( \delta \), the sparser the model.

III. MULTINOMIAL MANIFOLD

In this section, we briefly introduce the concept of multinomial manifold and the necessary ingredients used in the retraction-based framework of Riemannian optimization. The main notations on Riemann geometry on multinomial manifold in this section is summarized in Table I as a reference. We refer the readers to [24] for the general concepts of manifolds.

The multinomial manifold (also called a simplex) is the parameter space of the multinomial distribution defined by

\[
\mathbb{P}^N = \{ \beta = [\beta_1, \ldots, \beta_N]^T \in \mathbb{R}^N : \beta_j > 0, \ 1 \leq j \leq N, \beta^T 1 = 1 \} \quad (10)
\]

The multinomial manifold \( \mathbb{P}^N \) is an embedded Riemannian submanifold of the Euclidean space \( \mathbb{R}^N \) equipped with the so-called Fisher information metric \( g(\beta, \gamma) \) as [30], [31]

\[
g(\beta, \gamma) = \sum_{i=1}^{N} \frac{u_i v_i}{\beta_i} \quad (11)
\]

where \( u_\beta, v_\beta \in T_\beta \mathbb{P}^N \subset \mathbb{R}^N \) are tangent vectors to \( \mathbb{P}^N \) at \( \beta \), with their \( i \)-th elements defined as \( u_i \) and \( v_i \), respectively. The inner product on \( \mathbb{P}^N \) as defined in (11) determines the geometry, such as
distance, angle, and curvature on $\mathbb{P}^N$. Note that the tangent space $T_{\beta}\mathbb{P}^N$ at element $\beta$ can be described by
$$T_{\beta}\mathbb{P}^N = \{ u_{\beta} : u_{\beta}^T 1 = 0 \}. \quad (12)$$

### A. Riemannian Gradient

Let the Riemannian gradient of a scalar function $F(\beta)$ on $\mathbb{P}^N$ be denoted by $\text{grad}F(\beta)$, and its classical gradient as seen in the Euclidean space as $\text{Grad}F(\beta)$. Its gradient in $\mathbb{R}^N$ endowed with the metric $g$ is scaled as $\text{Grad}F(\beta) \odot \beta$, where $\odot$ is element-wise multiplication. We then have [31]
$$\text{grad}F(\beta) = \text{Proj}_\beta(\text{Grad}F(\beta) \odot \beta) \quad (13)$$
where $\text{Proj}_\beta(z)$ is the orthogonal projection into tangent space, which can be computed as
$$\text{Proj}_\beta(z) = z - \alpha \beta \quad (14)$$
where $\alpha = z^T 1$.

As a canonical way of identifying nearby tangent spaces, the Riemannian connection is typically given in the form of a covariant derivative which specifies how a tangent vector $v_{\beta}$ varies along the direction of another tangent vector $u_{\beta}$ on the manifold $\mathbb{P}^N$. To compute the Riemannian Hessian [24, Sec. 5.5], we need to use the notion of the Riemannian gradient on the manifold $\mathbb{P}^N$ denoted by $\nabla u_{\beta} v_{\beta}$. Since $\mathbb{P}^N$ is a Riemannian submanifold of $\mathbb{R}^N$ endowed with the metric $g$, the connection can be computed via
$$\nabla u_{\beta} v_{\beta} = \text{Proj}_\beta(\nabla u_{\beta} v_{\beta}) \quad (15)$$
where $\nabla u_{\beta} v_{\beta}$ is the connection on the manifold $\mathbb{R}^N$ endowed with the metric $g$. The connection $\nabla u_{\beta} v_{\beta}$ in $\mathbb{R}^N$ is computed using the Koszul formula, and after a few steps of computations it admits of matrix characterization [32]
$$\nabla u_{\beta} v_{\beta} = Dv_{\beta}[u_{\beta}] - \frac{1}{2} (u_{\beta} \odot v_{\beta}) \odot \beta \quad (16)$$
where $\odot$ denotes the element-wise division. $Dv_{\beta}[u_{\beta}]$ is the Euclidian direction derivative of $v_{\beta}$ in the direction of $u_{\beta}$.

### B. Riemannian Hessian

The Riemannian Hessian of $F(\beta)$ is defined as the connection
$$\text{Hess}F(\beta)[u_{\beta}] = \nabla u_{\beta} \text{grad}F(\beta)$$
$$= \text{Proj}_\beta \left( D\text{grad}F(\beta)[u_{\beta}] - \frac{1}{2} (u_{\beta} \odot \text{grad}F(\beta)) \odot \beta \right) \quad (17)$$
where $D\text{grad}F(\beta)[u_{\beta}]$ is the Euclidean gradient directional derivative of the Riemannian gradient in the direction of $u_{\beta} \in T_{\beta}\mathbb{P}^N$, which is calculated as
$$D\text{grad}F(\beta)[u_{\beta}] = D\text{Proj}_\beta(\text{Grad}F(\beta) \odot \beta)[u_{\beta}]$$
$$= D\text{Grad}F(\beta)[u_{\beta}] \odot \beta - D(\text{Grad}F(\beta) \odot \beta)^T 1[u_{\beta}]$$
$$= D\text{Grad}F(\beta)[u_{\beta}] \odot \beta + \text{Grad}F(\beta) \odot u_{\beta}$$
$$- (\text{Grad}F(\beta) \odot \beta)^T 1 u_{\beta} \quad (18)$$
by making use of (14) and (15), where $D\text{Grad}F(\beta)[u_{\beta}]$ is the Euclidean directional derivative of the Euclidean gradient $\text{Grad}F(\beta)$ in the direction $u_{\beta} \in T_{\beta}\mathbb{P}^N$.

### C. Retraction Mapping

An important concept in the recent retraction-based framework of Riemannian optimization is retraction mapping [24, Sec. 4.1]. The exponential map $\text{Exp}_{\beta}$ is the canonical choice for the retraction mapping; however, in this brief, we propose using the following standard approximation as the retraction mapping:
$$\beta_t = \text{R}_{\beta}(t u_{\beta}) := \frac{(\beta \odot \text{exp}(t(u_{\beta} \odot \beta)))}{(1^T (\beta \odot \text{exp}(t(u_{\beta} \odot \beta))))}$$
where $t$ is the called the step size, $\text{exp}(t)$ is an operator applied to matrices element by element. The retraction mapping is used to locate the next iterate on the manifold along a specified tangent vector, such as a search direction in line search in Newton’s algorithm or the suboptimal tangent direction in the trust-region algorithm, see [24, Ch. 7].

### IV. SPARSE DENSITY ESTIMATION USING RIEMANNIAN TRUST-REGION ALGORITHM

Since the constraint set of (2) is the multinomial manifold, our Riemannian optimization problem is simply formulated as
$$\min_{\beta \in \mathbb{P}^N} \left\{ F(\beta) = \frac{1}{2} \beta^T C_\beta - \beta^T p \right\}. \quad (19)$$
The RTR algorithm retains the superlinearly convergent properties of the Euclidean trust-region method of a second-order algorithm, and it is suitable for large-scale optimization on Riemannian manifolds [33], [34]. Each iteration consists of two steps: 1) approximating the solution of the so-called trust-region subproblem and 2) computing a new iterate based on a retracting mapping. The trust region subproblem is given by
$$\min_{u_{\beta} \in T_{\beta}\mathbb{P}^N, \|u_{\beta}\| \leq \Delta} F(\beta) + g(\text{grad}F(\beta), u_{\beta}) + \frac{1}{2} g(\text{Hess}F(\beta)[u_{\beta}], u_{\beta}) \quad (20)$$

Algorithm for sparse density estimation in Fig. 1. The RTR algorithm according to (13), (17), and (18).

For our objective function, it is easy to check that Euclidean function \( F \) from which the Riemannian gradient and Hessian of the objective function is used in PW estimator using grid search for an optimal kernel width. The SKD algorithm is also a regression-based pdf estimation method, in which the PW estimator is constructed and used as the desired response [19]. The RSDE-MNQP algorithm solves problem (7) using the MNQP algorithm [20]. Also aimed at solving (7), the FCR-MISE algorithm [23] formulates the density estimation in a forward constrained regression manner by selecting one kernel forwardly. We also point out that MISE cost function is used in PW estimator using grid search for an optimal kernel width. However, the kernel width for the other algorithm needs to be preset since its optimization process will become computational prohibitive.

Example 1: The density to be estimated for this 2-D example was given by the mixture of two densities of a Gaussian and a Laplacian, as defined by

\[
p(x) = \frac{1}{4\pi} \exp \left( \frac{-(x_1 - 2)^2}{2} \right) \exp \left( \frac{-(x_2 - 2)^2}{2} \right)
+ \frac{0.35}{8} \exp(-0.7(x_1 + 2)) \exp(-0.5|x_2|).
\]  
(24)

Example 2: The density to be estimated for this 6-D example was defined by

\[
p(x) = \frac{1}{3} \sum_{i=1}^{3} \frac{1}{(2\pi)^3 \sqrt{\det(G_1)}}
\times \exp \left( \frac{1}{2} (x - \mu_i)^T G_1^{-1} (x - \mu_i) \right)
\]  
(25)

where \( \mu_1 = [1.0, 1.0, 1.0, 1.0, 1.0, 1.0]^T \), \( \mu_2 = [-1.0, -1.0, -1.0, -1.0, -1.0, -1.0]^T \), \( \mu_3 = [0.0, 0.0, 0.0, 0.0, 0.0, 0.0]^T \), \( G_1 = \text{diag}(1.0, 2.0, 1.0, 2.0, 1.0, 2.0) \), \( G_2 = \text{diag}(2.0, 1.0, 2.0, 1.0, 2.0, 1.0) \), and \( G_3 = \text{diag}(2.0, 1.0, 2.0, 1.0, 2.0, 1.0) \).

The results for Examples 1 and 2 were listed in Table II(a) and (b), respectively. For the PW pdf estimator, the kernel width was determined by MSIE [2]. For RSDE-MNQP, FCR-MISE, and the proposed RTR-MISE algorithm, the kernel width was empirically set. The results for SDC, SKD, and FCR-MISE are quoted from [18], [19], [23], respectively. For the proposed RTR-MISE algorithm, we set \( \delta = 10^{-3} \) for both examples. It is seen that the proposed algorithm can construct sparse kernel density estimators with an accuracy competitive with those of a PW estimator and other existing sparse kernel density estimators.
