Chemistry and Structure by Design: Ordered CuNi(CN)$_4$ Sheets with Copper(II) in a Square-Planar Environment

A. M. Chippindale,* S. J. Hibble,* E. Marelli, E. J. Bilbe, A. C. Hannon and M. Zbiri
Layered copper-nickel cyanide, CuNi(CN)$_4$, a 2-D negative thermal expansion material, is one of a series of copper(II)-containing cyanides derived from Ni(CN)$_2$. In CuNi(CN)$_4$, unlike in Ni(CN)$_2$, the cyanide groups are ordered generating square-planar Ni(CN)$_4$ and Cu(NC)$_2$ units. The adoption of square-planar geometry by Cu(II) in an extended solid is very unusual.

The simple binary copper(II) cyanide, Cu(CN)$_2$, does not exist. The reaction of Cu(II) in aqueous solution with the pseudohalide cyanide ion reacts via a number of steps to produce cyanogen and copper(I) cyanide, CuCN. This is reminiscent of the reaction familiar to chemistry undergraduates in which the iodide ion reacts with copper(II) to produce iodine and copper(I) iodide.

2Cu$^{2+}$ + 4 X$^- = 2CuX + X_2$ (X = I$^-$, CN$^-$)

Our challenge was to stabilize Cu(II) with respect to the internal redox reaction in the presence of cyanide ligands only. This has been achieved by replacement of half of the Ni(II) in anhydrous nickel cyanide, Ni(CN)$_2$, by Cu(II) to form CuNi(CN)$_4$. In Ni(CN)$_2$, each Ni atom is linked by four linear, bridging cyanide ions to four other nickel atoms to form planar Ni(CN)$_2$ sheets with head-to-tail cyanide disorder. By using the square-planar ion, [Ni(CN)$_4$]$^{2-}$, as a synthon and linking such units by Cu$^{2+}$ ions, a modified Ni(CN)$_2$ sheet structure can be assembled in which the copper atoms have square-planar geometry and are coordinated only to cyanide ligands via nitrogen to generate an ordered sheet (Figure 1).

Although there are a number of examples of molecular species containing square-planar Cu(II) with, for example, phthalocyanines and N and O donor ligands, we believe that the layered product, CuNi(CN)$_4$, is the first example of a simple extended solid containing Cu$^{2+}$ (d$^9$) ions in X-ray diffraction patterns of CuNi(CN)$_4$ at 30, 180 and 270 °C (303, 453 and 543 K) square-planar coordination. The separation between adjacent CuNi(CN)$_4$ layers at 3.09 Å is too great for significant interlayer interactions to occur, precluding Jahn-Teller distortion of octahedral geometry to produce (4+2) coordination, as is frequently observed in Cu$^{2+}$ compounds. Further exploration of the Cu(II)-Ni(II) cyanide phase diagram shows that Cu(II) containing compounds also exist both as hydrates, Cu$_x$Ni$_{1-x}$(CN)$_2$·3H$_2$O, and dehydrated phases, Cu$_x$Ni$_{1-x}$(CN)$_2$, forming solid solutions over the range (0 ≤ x ≤ 0.25).

The addition of Cu$^{2+}$ ions to Ni(CN)$_2$ in aqueous solution immediately produces a blue-green gelatinous precipitate (vide infra), which on stirring for several hours transforms to a grey solid, characterised as CuNi(CN)$_4$. On heating CuNi(CN)$_4$ under nitrogen at 680 K, copper(II) is reduced by cyanide to produce copper(I) cyanide and paracynogen, together with nickel cyanide, according to the reaction:

Cu$^{2+}$Ni(CN)$_4$ = Ni(CN)$_2$ + CuCN + (CN)$_6$

Figure 2 shows the powder X-ray diffraction patterns obtained for CuNi(CN)$_4$ and Ni(CN)$_2$. The Bragg peak positions and relative intensities show the close underlying similarity of the two structures and confirm that CuNi(CN)$_4$ is a layered material. The difference in peak widths in the two diffraction patterns arises mainly from the difference in crystallite size of the two materials. The Raman spectrum of CuNi(CN)$_4$ exhibits 2 $\nu_{CN}$ stretches, at 2209 and 2184 cm$^{-1}$, and the infrared spectrum has one non-coincident $\nu_{CN}$ stretch at 2182 cm$^{-1}$. These observations are consistent with $D_{3h}$ symmetry of the individual metal-cyanide layers. Only two arrangements of the metal atoms and cyanide groups within each layer are therefore possible: namely, the one shown in Figure 1, with the carbon end of the cyanide ligand attached to nickel and the nitrogen end to copper, or the inverted arrangement with the carbon end attached to copper. Of these two possibilities, only the first arrangement yields a good fit to the low r region (0 < r / Å < 3) of the total correlation function, $T^0(r)$exp, obtained from neutron diffraction (Figure 3 and S.10) confirming that the metals and cyanide groups in CuNi(CN)$_4$ are indeed arranged as shown in Figure 1. The bond lengths obtained from the fitting of individual peaks in $T^0(r)$exp at 15 K are: C=N, 1.1541(6); Ni=C, 1.857(1) and Cu–N, 1.943(2) Å.

Fig. 1 Representation of a layer of CuNi(CN)$_4$ with square-planar geometry around both Cu$^{2+}$ and Ni$^{2+}$ ions. The structural repeat unit within the layer is shown in the red square of length a.

Fig. 2 Powder X-ray diffraction patterns at 295 K of (a) CuNi(CN)$_4$ (a = 6.957(1) Å and c = 12.802 Å) and (b) Ni(CN)$_2$ (a = 4.857 Å and c = 6.180 Å) showing Miller indices of the principal reflections.

Taking into account the metal and cyanide ordering within the layers determined above, the powder X-ray diffraction pattern for
CuNi(CN)$_4$ can be indexed on a tetragonal unit cell (a = 6.957(1) Å and c = 9.180(6) Å) (Figure 2). This unit cell is related to that of Ni(CN)$_2$. The a lattice parameter in CuNi(CN)$_4$ is ~<0.2 of the value for Ni(CN)$_2$ as a consequence of the ordering of the Cu and Ni atoms within the layers. X-ray and neutron diffraction experiments$^3$ show no evidence of cyanide ordering within the nickel-cyanide layers in Ni(CN)$_2$ and in this case, the A lattice parameter corresponds to the direct M–CN–M distance shown in Figure 1. The c lattice parameter chosen for CuNi(CN)$_4$ corresponds to a two-layer repeat, ABAB, and a physically reasonable interlayer separation of ~3.09 Å. Although a c lattice parameter of 1/2 this value could be used to index fully the powder X-ray pattern of CuNi(CN)$_4$, this would be physically unreasonable as in the resulting AAA stacking, the atoms in adjacent layers would lie directly above each other and hence be impossibly close together. The stacking sequence in Ni(CN)$_2$ is more complicated with a four-layer repeat predominating. Using the Cu–N, Ni–C and C≡N bond lengths obtained from fitting the low r region of $\langle T^2(r)\rangle_{\text{exp}}$ (Figure 3), together with the unit-cell parameters obtained from the powder X-ray diffraction pattern and including the ABAB stacking of the layers, a 3-D model was constructed in space group Cmcm (Figure 4). This model reproduces $\langle T^2(r)\rangle_{\text{obs}}$ to r = 15 Å well (Figure 3) and is thus a good representation of the short- and medium-range structure in the material.$^1$ It should be noted that this conventional crystallographic model does not fully reproduce the powder X-ray diffraction pattern in Figure 2 because in CuNi(CN)$_4$, there is extensive stacking disorder, as evidenced by the shape of the (110) reflection (Figure 2). Hence although the model gives a good description of the short- and medium-range order in CuNi(CN)$_4$, the chemically important information, it needs to be combined with a model of the stacking disorder in order to reproduce the powder X-ray pattern. Indeed, an appropriate calculation demonstrating this has already been carried out in a previous paper$^4$ in which different types of stacking disorder were considered for Ni(CN)$_2$ and has validity in the present case as the X-ray scattering factors of Cu and Ni are very similar (as indeed are those of C and N). The simulated powder X-ray diffraction pattern in which the sequence AB is followed by A occurs with a probability of 75% gives a good match to our observed pattern. In contrast, in Ni(CN)$_2$, the most probable stacking sequence (67%) is that the sequence AB is followed by a third layer, A’, which is offset with respect to both A and B.

Layered inorganic materials are currently attracting much interest, particularly with respect to their electronic, optical and mechanical properties.$^5$ Although graphene and metal sulfides are the most widely studied, a recent paper utilising DFT calculations has suggested that Ni(CN)$_2$ should have interesting electronic properties when in the form of individual sheets and, by analogy with graphene, when rolled into nanotubes, particularly if it can be n or p doped.$^6$ Mo and Kaxiras proposed that doping could be achieved by replacing some of the –C≡N– linkages by –CC=C– or –N≡N– groups to produce either p- or n-doped structures. In our synthesis of CuNi(CN)$_4$, we have effectively substituted on the metal sites in Ni(CN)$_2$, rather than the non-metal sites. By replacing half the Ni$^{2+}$ by Cu$^{2+}$ in Ni(CN)$_2$ to form CuNi(CN)$_4$, we have achieved an extremely high level of n doping of the layers. The magnetic susceptibility of CuNi(CN)$_4$ has the value $\mu = 1.76$ $\mu_B$ at 295 K, which is consistent with isolated moments on Cu$^{2+}$ ions (d$^9$), and unfortunately indicates that a delocalised electron system is not formed. The presence of an absorption band centred at ~17000 cm$^{-1}$ in the diffuse reflectance spectrum of CuNi(CN)$_4$ can be ascribed to a d-d transition(s) and is unobserved in the corresponding spectrum of Ni(CN)$_2$ (Figure 5). From the reflectance spectra, the optical band gaps for Ni(CN)$_2$ and CuNi(CN)$_4$ are determined to be 16100 and 21780 cm$^{-1}$ (2 and 2.7 eV), respectively, showing that this degree of substitution of Ni by Cu has produced a poorer semiconductor as a result of ordering within the metal-cyanide sheets.

Fig. 3 Total correlation functions for CuNi(CN)$_4$ at 15 K: $\langle T^2(r)\rangle_{\text{exp}}$ (black line) and, for a model in Cmcm, $\langle T^2(r)\rangle_{\text{obs}}$ (red line). The difference function is shown at the bottom of the plot (offset for clarity by 1 barns Å$^2$).

Fig. 4 Model of CuNi(CN)$_4$ in space group Cmcm (a = b = 9.9082 Å and c = 6.100 Å) showing the ABAB stacking of the ordered layers. (Key: copper atoms, orange spheres; nickel atoms, black spheres; carbon atoms, green spheres and nitrogen atoms, blue spheres).

Fig. 5 Diffuse reflectance spectra of CuNi(CN)$_4$ (red) and Ni(CN)$_2$ (black).
Considering mechanical properties, CuNi(CN)$_4$ shows two-dimensional negative thermal expansion with $\alpha_a = -9.7(8) \times 10^{-6}$ K$^{-1}$ (where $\alpha_a = \frac{1}{a} \frac{\partial a}{\partial T}$) which is of a similar magnitude to that measured for graphite$^1$ and $\sim 1.5$ times the value for Ni(CN)$_2$. Inelastic neutron scattering and DFT studies on Ni(CN)$_2$ at ambient$^2$ and high pressure$^3$ show that it is the atomic motions perpendicular to the metal-cyanide sheets that give rise to the 2-D NTE behaviour and it is anticipated that similar mechanism will apply in the case of CuNi(CN)$_4$. Figure 6 shows the relative percentage changes in the $a$ and $c$ lattice parameters and cell volume, $V$, for CuNi(CN)$_4$ and Ni(CN)$_2$. Although $\alpha_a$ is independent of temperature over the temperature range of this study for both CuNi(CN)$_4$ and Ni(CN)$_2$, the temperature dependence of $\alpha_a$ is different for the two materials. For CuNi(CN)$_4$, $\alpha_a$ is non linear with temperature, whereas for Ni(CN)$_2$, it is, like $\alpha_a$, independent of temperature. An explanation of the difference in the form of the variation of the $c$ parameter with temperature, and hence also cell volume, requires a detailed comparison of the phonon density of states of CuNi(CN)$_4$ and Ni(CN)$_2$ to be carried out over a comparable temperature range.

As well as being mechanically different from Ni(CN)$_2$, copper nickel cyanide, CuNi(CN)$_4$, is chemically different in that it does not form hydrates. Indeed, it can be obtained directly from aqueous solution as the anhydrous compound, as described above. Similar reactions using only nickel reagents, e.g. Ni$^{2+}$ + Ni(CN)$_2$$^{2-}$, produce layered nickel-cyanide hydrates, Ni(CN)$_2$$\cdot$H$_2$O (n = 3, 3/2), containing Ni(NC)$_3$(H$_2$O) and Ni(CN)$_2$ units, and dehydration is required to form Ni(CN)$_2$.$^3$

CuNi(CN)$_4$ is probably initially formed as individual layers. Mixing the salt solutions produces at first a blue gel, which turns grey on ageing in solution or on drying as the individual layers aggregate to form stacks. The powder X-ray diffraction patterns shown in Figure 7 provide evidence that the material grows only slowly in the [001] direction. Even in its final grey form, the stacks in CuNi(CN)$_4$ are only $\sim$40 Å thick (as estimated by using the Scherrer equation applied to the (002) reflection). The slow growth in the $c$ direction occurs possibly because the bonding between the layers is weak. Support for this hypothesis comes from the ease of separating the layers to make intercalation compounds. For example, stirring CuNi(CN)$_4$ in 4,4'-bipyridine in ethanol at room temperature produces a blue-grey solid with an interlayer separation of $\sim$11.3Å, consistent with the formation of a pillared-layer compound. CuNi(CN)$_4$(bipy)$_2$, which is distinct from the previously reported material, CuNi(CN)$_4$(bipy)$_2$(H$_2$O)$_{13}$, in which $\text{Cu(OH)}_2\cdot\text{NC}$–Ni(CN)$_2$–CN– zig-zag chains are linked through 4,4'-bipyridine groups.

Further exploration of the CuCN$\cdot$NiCN$\cdot$ phase diagram required a different method of synthesis in which Cu$^{2+}$ and Ni$^{2+}$ were simultaneously added to a cyanide solution. Using this method at more nickel-rich compositions than CuNi(CN)$_4$ ((Cu$_{3}$Ni$_{10}$CN$_{16}$), mixtures of CuNi(CN)$_4$ and the hydrate Cu$_4$Ni$_{14}$CN$_{20}$·3H$_2$O were produced. At even higher nickel contents, a solid-solution region, Cu$_{x}$Ni$_{1-x}$CN$_{2}$$\cdot$3H$_2$O (0 $\leq$ x $\leq$ 0.25), formed. The hydrates can be easily dehydrated to form the Cu$_{x}$Ni$_{1-x}$CN$_{2}$ phases shown in Figure 8, which all adopt a nickel-cyanide-type structure. No mixed Cu(II)-

![Fig. 6 The relative percentage changes in the a and c lattice parameters and volume, V, for CuNi(CN)$_4$ and Ni(CN)$_2$.](image)

![Fig. 7 In situ powder XRD patterns collected during the drying of CuNi(CN)$_4$ as the sample turned from a blue-green gelatinous solid to a grey powder.](image)

Ni(II) cyanides containing more copper than nickel could be prepared and the additional copper Cu(II) is reduced to Cu(I) in the form of the low-temperature polymorph of copper (I) cyanide, LT-CuCN$^{14}$, This reduction was also found when preparing the mixed Cu(I)-Cu(II) phase, Cu$_2$Ni$_{1-x}$CN$_{2}$·3H$_2$O, from Cu(II) and Ni(CN)$_2$$^{2-}$.$^{15}$ In copper rich compounds, Cu$_{x}$Ni$_{1-x}$CN$_{2}$$^{2-}$ (x $\geq$ 0.5), some Cu(II) atoms would have to be coordinated to the carbon end of cyanide groups and it might be this fact that leads to their instability. Although rare, it should be noted that Cu(II) can be attached to cyanide groups via the carbon end of the ligand, for example, in $\text{Cu(phen)}_2\cdot\text{CN}$$^{16}$ and of particular note is the molecular compound, $\text{Cu(phen)}_2\cdot\text{CN}$$^{2-}$, which has Cu(II) connected to two CN groups in this way.$^{17}$

In conclusion, we have prepared a number of new layered compounds, Cu$_x$Ni$_{1-x}$CN$_{2}$$^{2-}$ consisting of M(CN)$_2$ sheets structurally related to those found in Ni(CN)$_2$. Addition of the synthon, [Ni(CN)$_2$]$^{2-}$ to Cu$^{2+}$ in aqueous solution, leads to the precipitation of anhydrous CuNi(CN)$_4$. A combination of powder X-ray and total neutron diffraction, together with vibrational spectroscopy, has established that in CuNi(CN)$_4$ ((Cu$_{3}$Ni$_{10}$CN$_{16}$)), the cyanide ligands bind so that their carbon atoms are coordinated only to nickel
and their nitrogen atoms only to copper to generate ordered sheets containing square-planar Ni(CN)\(_4\) and Cu(NC)\(_3\) units. The stabilising of Cu\(^{II}\) in an environment with cyanide as the only ligand present has not previously been reported. CuNi(CN)\(_3\) shows two-dimensional negative thermal expansion. We are currently analysing the phonon density of states of CuNi(CN)\(_3\) to discover why it shows very different thermal expansion behaviour from Ni(CN)\(_2\) perpendicular to the metal-cyanide layers.

In contrast to CuNi(CN)\(_3\), which can be prepared directly as an anhydrous compound from aqueous solution, other, more nickel-rich CuNi\(_{1-x}\)(CN)\(_2\) compounds are formed via the hydrates, CuNi\(_{1-x}\)(CN)\(_3\)-3H\(_2\)O, which can be easily dehydrated. A solubility gap exists between CuNi(CN)\(_3\), the most copper-rich phase that can be formed, and a region of solid solution which exists between Cu\(_{1/2}\)Ni\(_{3/4}\)(CN)\(_2\) and Ni(CN)\(_2\).

FOOTNOTE: Although ordering of cyanide groups often occurs in mixed-metal cyanides, this is not always the case. For example, in the series of mixed-metal cyanides containing Cu(I), (Cu\(_{1/2}\)Au\(_{1/2}\))CN contains ordered chains of the type [Au−C≡N−Cu−N≡C−]\(_n\) whereas in (Cu\(_{1/2}\)Ag\(_{1/2}\))CN, there is head-to-tail cyanide disorder.†

‡FOOTNOTE: Although stacking together layers of D\(_8\)h symmetry in an ABAB sequence is incompatible with true tetragonal symmetry, it is possible to construct orthorhombic models with a tetragonal metric. Furthermore, stacking disorder will lead to the long-range average metric appearing tetragonal, so that a model describing the local and intermediate structure in Cmcm is not in conflict with the indexing of the powder X-ray pattern as tetragonal.

Graphical Abstract

Cu(II) has been stabilised with square-planar coordination in a cyanide-only environment in the layered semiconductor material, copper-nickel cyanide, CuNi(CN)\(_3\), which shows 2-D negative thermal expansion.
