Abstract

BACKGROUND: Little is known about native and non-native rodent species interactions in complex tropical agro-ecosystems. We hypothesised that the native non-pest rodent *Rattus everetti* may be competitively dominant over the invasive pest rodent *Rattus tanezumi* within agroforests. We tested this experimentally by using pulse removal for three consecutive months to reduce populations of *R. everetti* in agroforest habitat and assessed over 6-months the response of *R. tanezumi* and other rodent species.

RESULTS: Following removal, *R. everetti* individuals rapidly immigrated into removal sites. At the end of the study period, *R. tanezumi* were larger and there was a significant shift in their microhabitat use with respect to the use of ground vegetation cover following the perturbation of *R. everetti*. Irrespective of treatment, *R. tanezumi* selected microhabitat with less tree canopy cover, indicative of severely disturbed habitat, whereas, *R. everetti* selected microhabitat with a dense canopy.

CONCLUSION: Our results suggest that sustained habitat disturbance in agroforests favours *R. tanezumi*, whilst the regeneration of agroforests towards a more natural state would favour native species and may reduce pest pressure in adjacent crops. In addition, the rapid recolonisation of *R. everetti* suggests this species would be able to recover from non-target impacts of short-term rodent pest control.

Interspecific competition, Microhabitat use, Pest management, *Rattus everetti, Rattus tanezumi*, Removal experiment
1 Introduction

Rodentia is the most diverse group among mammals with over 2050 species described, of which many are endemic to large or remote oceanic islands.1, 2 Oceanic islands, however, are often recognised for their vulnerability to non-native rodent invasions due to a lack of functionally equivalent competitors, mainly because of poor native rodent assemblages, as well as a lack of natural predators.3, 4 On the other hand, oceanic islands that have high rodent endemism are more likely to have species that can successfully compete against invasive rodent species in natural ecosystems.5 However, there are few studies that have investigated interactions between native and non-native rodent species in invaded ecosystems.6-8 In addition, anthropogenic activities, such as urbanisation, deforestation and agriculture, on oceanic islands with high rodent endemism have caused the degradation of many natural habitats, leading to both a decline in the abundance and diversity of endemic rodent species2, 9 and an increase in the abundance of non-native pest rodent species that can cause severe crop losses and have devastating effects on native fauna.6, 10 Non-native rodent species also have been implicated in reducing the distribution and abundance of native small rodents due to competition for limited resources and the spread of new diseases.11

The Philippines is an oceanic archipelago recognised for its high rodent diversity and endemism, with over seventy murid rodent species described.2, 12 The majority of endemic rodent species in the Philippines are restricted to habitats that experience minimal habitat disturbance, such as natural forest ecosystems.9, 12 None of these endemic rodents are considered to be pests,12 whereas, the five rodent species considered pests, are considered to be non-native in origin, and generally inhabit highly disturbed areas.12 These species are Rattus tanezumi (Temminck), Rattus exulans (Peale), Rattus argentiventer (Robinson and Kloss), Rattus norvegicus (Berkenhout) and
Mus musculus domesticus (Linnaeus); their occurrence and relative abundance appears to increase with increasing habitat disturbance, with few trapped in forests, even when adjacent to agricultural land.\textsuperscript{9, 14-16} In complex agricultural landscapes that include habitats such as agroforest, grassland, riparian, and various agricultural crops, both native and non-native rodent species co-exist.\textsuperscript{13, 17-19} These commonly include the endemic non-pest species, Rattus everetti (Gunther) (common Philippine forest rat) and Chrotomys mindorensis (Kellogg) (striped shrew-rat), and the invasive pest species, R. tanezumi and R. exulans. However, little is known about the interactions that take place between native and non-native rodent species in these habitats.

Recent studies on the interaction between native and invasive rodent species highlight that targeted manipulation of population densities or habitat could favor native species and provide a basis for minimising the negative impact of invasive species on agricultural production,\textsuperscript{11} human health\textsuperscript{12} or biodiversity.\textsuperscript{20} In eastern Australia, Stokes et al.\textsuperscript{5} reported that a native rodent, Rattus fuscipes, was able to suppress the invasive rodent, Rattus rattus, in disturbed forest habitat. In eastern Africa, Taylor et al.\textsuperscript{21} reported that the main agricultural rodent pest, Mastomys natalensis, was the dominant species in croplands when the small mammal community was sparse, whereas it was less common when the small mammal community was diverse. In response to these findings, Banks et al.\textsuperscript{20} proposed that the reintroduction of a native rodent, R. fuscipes, following removal of R. rattus, could reduce the reinvasion success of R. rattus, at the urban-bushland interface,\textsuperscript{11} and lead to biodiversity benefits, and Taylor et al.\textsuperscript{21} suggest encouraging heterogeneous habitats on crop margins to favour a diverse native small mammal communities. Previous studies in the Philippines suggest that non-native pest species of rodents are restricted to heavily disturbed areas except where the diversity and abundance of native species are low.\textsuperscript{22-24} For example, in the lowland agro-ecosystems of the Sierra Madre Biodiversity Corridor, northern Luzon, R. tanezumi is the most abundant rodent species in a variety of agricultural habitats, including rice fields and

This article is protected by copyright. All rights reserved.
coconut groves, where few native rodents are present.\textsuperscript{17, 25} However, in agroforest ecosystems, a moderately disturbed hillside habitat comprised of coconut trees interspersed with other trees, the abundance of \textit{R. tanezumi} is low, whereas the abundance of the larger native rodent \textit{R. everetti} is high.\textsuperscript{17} \textit{R. everetti} is an ecological generalist that is tolerant of a wide variety of habitats and appears to prefer moderately disturbed habitat;\textsuperscript{9, 15} thus, it may block or inhibit \textit{R. tanezumi} from establishing within agroforest because of interspecific competition.\textsuperscript{15, 17}

\textit{R. tanezumi} is a serious pest of rice and coconut in the Philippines, with reported rice yield losses of up to 50 \% in some regions of Luzon.\textsuperscript{26, 27} In an effort to control rodent pests in the Philippines, farmers often apply rodenticides and periodically remove regenerating second growth vegetation that are perceived to provide refugia for pest rodents. The latter creates highly disturbed habitat that is considered to be less suitable for native non-pest rodents and more suitable for non-native pest rodents.\textsuperscript{9, 14, 15} If \textit{R. everetti} is competitively dominant over \textit{R. tanezumi} in agroforest habitat, any form of control that has a negative effect on \textit{R. everetti} populations may be counterproductive, resulting in an increase in the pest species.

We conducted a pulse perturbation experiment\textsuperscript{28} to assess the response of the rodent community following pulsed removal of \textit{R. everetti} from an agroforest habitat. Interspecific competition is considered to have a negative effect on the fitness of individuals by effecting reproduction, growth and/or survival.\textsuperscript{29, 30} We hypothesise that a reduction of the \textit{R. everetti} population reduces competitive pressure on \textit{R. tanezumi}, and we would expect a concomitant increase in the reproduction rates, growth rates and/or survival of \textit{R. tanezumi}. Furthermore, if interference competition has been operating, we would expect an increase in abundance by immigration of \textit{R. tanezumi} following removal of \textit{R. everetti} individuals.

Differential resource selection is recognised as one of the principal relationships which permit species coexistence.\textsuperscript{31, 32} Resources are considered to be selected when they are used in
higher proportion to their availability. However, the habitat selected by an individual may not be its preferred choice if it is affected by intra- or interspecific competition, such as territoriality or competition for food. The agroforest ecosystem is comprised of a heterogenous vegetation structure. We assessed microhabitat use to determine whether the vegetation structure was a significant factor influencing R. tanezumi and R. everetti distribution within agroforest habitat and whether perturbation of R. everetti had an effect.

By removing R. everetti from agroforest populations, we are simulating a non-target impact of lethal rodent pest control on R. everetti, such as would likely result from rodenticide application in habitats adjacent to rice fields to target rodent pests of rice. We therefore investigated the population recovery of R. everetti in agro-ecosystems following short-term lethal control.

2 Materials and methods

2.1 Study area

The study was conducted in the Municipality of Baler, Aurora, Philippines (15° 73’N; 121° 56’E). Aurora province is located on the mid-eastern coast of Central Luzon (Region III), and covers the eastern portion of the Sierra Madre Mountain Range. Aurora has a land area of 324,000 hectares, of which, 230,000 hectares (71%) is covered by forest. Thirty percent of Aurora is coastal flatland, where 50,000 ha are cultivated for agriculture. The forests occur mainly in mountainous areas that cover most of the province.

The study sites were located in coconut-based agroforest habitat, located on the lower slopes of hillsides, at an elevation of 30-70 m asl. The coconut trees were interspersed with small trees valued for timber and firewood, and perennial crops such as banana and citrus. There was a
heterogeneous vegetation structure with patches of open canopy and dense understory vegetation. There was typically 25-75% canopy cover and 25-100% undergrowth vegetation cover. At higher elevation (45 - 100 m asl), above the agroforest habitat, secondary lowland forest was present. At low elevation (0 - 20 m asl), rice fields were located 25-130 m from the study sites. There are no distinct wet or dry seasons in the study area, with rainfall distributed more or less evenly throughout the year. The average monthly rainfall is 273.9 mm, with extreme rainfall events most likely to occur between October and December. The annual average temperature is 25.3°C, the warmest months are June and July and the coolest are January and February.

2.2 Experimental design

Four different sites situated in agroforest habitat were selected that were similar in vegetation structure. At each site, a trapping grid of 42 (6 x 7) locally-made single-capture live cage-traps (300 x 140 x 140 mm) was set. Traps were spaced 15 m apart, giving a grid area of 6750 m². The effective trapping area is expected to be larger than the actual grid area as animals are also attracted to traps from an area surrounding the trapping grid. Trapping sites were at least 500 m apart (no individual rodents were caught at more than one site).

Trapping was conducted monthly from May to October 2007. Traps were ‘pre-baited’ for three nights before the trapping session began. Traps were set for four consecutive nights. Traps were baited in the morning with coconut pieces combined with a live golden apple snail (*Pomacea canaliculata* Lamarck) to increase diversity of species captured. They were checked each morning beginning at dawn. Trapped animals were identified to species, sexed and individually marked with a combination of ear punches (see Stuart *et al.* for further details). Body measurements were recorded and female breeding condition was determined according to Aplin *et al.*
Two treatment sites were randomly selected for *R. everetti* removal and there were two non-treatment sites for comparison. In the treatment sites, all *R. everetti* individuals trapped on the 1\textsuperscript{st} night were released to enable an estimate of population abundance using mark-recapture methods. On the 2\textsuperscript{nd}, 3\textsuperscript{rd} and 4\textsuperscript{th} nights, all *R. everetti* individuals were removed and euthanased. *R. everetti* removal trapping was conducted over the first three trapping sessions, each a month apart. This was followed by three monthly sessions of non-removal trapping to estimate the recovery of *R. everetti* populations. During each month, all sites were trapped within a two-week period and the stage of the rice crop nearest each site was recorded.

To assess effectiveness of live-traps and to obtain an additional measure of abundance, kill-traps (break-back traps) were set in all sites during the final trapping session in October 2007, for an additional three nights immediately after live-trapping. Kill-traps were placed in the same location as live-traps and were baited with coconut only.

Traps occasionally went missing or were sprung by terrestrial hermit crabs (*Coenobita* sp.). These traps were excluded from the total number of traps nights.

2.3 Microhabitat

At each trap station, the vegetation structure (‘microhabitat’) was assessed by measuring the following physical features:

i. Ground vegetation cover – measured by visually estimating and averaging the percentage of a circular quadrate of one metre radius covered with vegetation less than 10 cm in height (such as grass, moss or leaf litter). The quadrate was centred on the trap entrance.
ii. Understorey vegetation cover - measured by visually estimating and averaging the percentage of a quadrat of one metre radius covered with vegetation with a height between 10 cm and 2 m (such as shrubs and ferns).

iii. Canopy cover - measured by visually estimating and averaging the percentage canopy cover, from vegetation more than 2m in height, above the trap.

iv. Understorey vegetation height – measured directly above the trap entrance.

Categories of percentage vegetation cover were: less than 25%, 25-49%, 50-74%, and more than 74%. The microhabitat at each trap station was measured during each trapping session by a single experimenter to avoid bias

2.4 Analyses

Statistical analyses were carried out using SPSS version 18 (SPSS Inc., Chicago, IL, USA). The mean number of individuals caught per trap grid for every 100 trap nights (excluding recaptures within trapping sessions) provided an index of the relative abundance of animals per trapping effort (no. caught per 100 trap nights). Linear mixed models with maximum likelihood estimation were used to analyse differences in relative abundance (ln Y + 1) over time and between treatments for the three most commonly trapped species, *R. everetti*, *C. mindorensis* and *R. tanezumi*. Fixed effects entered into the model included month (as a repeated variable with diagonal repeated covariance), treatment, species and all interactions. Trapping sites were entered as random effects. Using *R. everetti* capture data, for which suitable mark-recapture data were available, *R. everetti* abundance estimates were verified using Huggins closed captures models in Program MARK\textsuperscript{35} that simultaneously incorporated mixture models and sex as a covariate to
model heterogeneity in the data when estimating population size.\textsuperscript{36, 37} For increased precision, data were pooled within treatments. Recapture rates for \textit{R. tanezumi} and \textit{C. mindorensis} were insufficient for mark recapture analyses.

\textit{R. tanezumi} are known to migrate between rice fields and adjacent habitats at different crop stages, moving into the rice fields when there is sufficient cover provided by the mid-tillering crop and into adjacent habitats during land preparation, when the rice habitat is disturbed.\textsuperscript{37, 38} To investigate whether the stage of the nearby rice crop influenced \textit{R. tanezumi} abundance in agroforest habitat, linear mixed models of \textit{R. tanezumi} abundance between treatments and crop stages was calculated; with crop stage categorised as either vegetative (seedling to tillering), generative (booting to ripening) or stubble (post-harvest) and trapping sites entered as random effects.

Low recapture rates of \textit{R. tanezumi} and \textit{C. mindorensis} precluded the analysis of growth and survival. Thus, indices of body condition were used to measure fitness.\textsuperscript{29, 39} Indices of condition were constructed by estimating body condition based on a regression between skeletal size (head and body length) and body mass.\textsuperscript{40} The regression equations obtained by Stuart\textsuperscript{37} using a 18-month data set were used to calculate the index of condition for first captures and monthly recaptures of adult \textit{R. tanezumi} (≥ 140 mm), \textit{R. everetti} (females: ≥ 173 mm, males: ≥ 180 mm) and \textit{C. Mindorensis} (≥ 135 mm). Adults were classified based on the head and body length below which ≤ 5 % of females and ≤ 10 % of males were sexually mature.\textsuperscript{37} Pregnant females were omitted.

Linear mixed models were used to analyse condition index and body size (head and body length) against month, treatment and sex. All interactions were included and trapping sites were included as random effects. Each species was analysed separately. To reduce variance, juvenile \textit{R. tanezumi} and \textit{C. mindorensis} were excluded from the analysis of body size due to low numbers of
captures. Linear mixed models were also used to test for differences in the proportion of females captured between species, treatment and month. Binary logistic regression was used to investigate whether *R. everetti* removal influenced the occurrence of adult females in breeding condition. Independent variables entered into the model were treatment, trapping period (May; June-October), site and the treatment x trapping period interaction. Trapping sessions from June to October were pooled due to low sample size. For the analysis of *R. tanezumi*, crop stage was included as a covariate.

To assess *R. everetti* and *R. tanezumi* ‘microhabitat’ selection and whether this was influenced by *R. everetti* removal, we performed binary logistic regression analysis of trap occupancy (presence; absence) in relation to vegetation cover. Logistic regression was used to model the resource selection probability function, i.e. the probability that a resource unit, i.e. vegetation cover, is used given census information on which units were used or available in the study area. Independent variables entered into the full model were month, trapping site, treatment, vegetation (understorey, ground, canopy) cover, treatment x vegetation cover and month x treatment x vegetation cover. Non-significant variables (p > 0.05) were removed sequentially using the backward elimination technique and the significance of each variable was assessed by analysing the difference in the model log-likelihood statistic with and without the variable present. Univariate GLM was used to analyse the effect of mean vegetation height (square-root transformed) on trap occupancy (presence/absence).
3 Results

During six sessions of live-trapping, from May to October 2007, and 3668 trap nights (excluding 364 trap nights due to missing or sprung traps with no capture), we captured 155 *R. everetti* individuals (387 captures), 118 *R. tanezumi* individuals (146 captures), 50 *C. mindorensis* individuals (118 captures), nine *R. exulans* individuals (12 captures), and five *Bullimus luzonicus* (Thomas) individuals (12 captures) (Table S1). During the removal trapping sessions, the *R. everetti* population in each treatment site was reduced by at least two thirds (Table 1). Aside from a few exceptions, the abundance estimates were in general agreement with the estimated population size calculated using Huggins closed captures models, indicating that *R. everetti* capture rates were high (Table 2).

During the last trapping session, 13 *R. tanezumi* individuals and 17 *R. everetti* individuals were trapped using kill-traps (Table S1). Seven were new *R. tanezumi* individuals, two were recaptures from a previous session and four were recaptures from the same session. One new *R. everetti* individual was captured using kill-traps, four were recaptures from a previous session and 12 were recaptures from the same session.

3.1 Rodent population responses following the short-term removal of *R. everetti*

Of the three most commonly trapped rodent species, *R. everetti* was the most abundant and *C. mindorensis* was the least abundant (F_{2,61.5} = 49.462, P < 0.001) (Figure 1). Removal of *R. everetti* had no significant effect on abundance (F_{1,3.8} = 0.017, P = 0.904), but the interaction between abundance and time differed between species (F_{10,22.4} = 5.102, P = 0.001). In both treatment and non-treatment sites, the abundance of *R. everetti* declined from May to July and gradually
recovered to pre-treatment levels by October, whereas the abundance of *R. tanezumi* and *C. mindorensis* showed no clear pattern, aside from a slight decline from August to October. The stages of the nearby rice crop did not influence the abundance of *R. tanezumi* in agroforest habitat ($F_{2,20.6} = 2.330, P = 0.144$) and no other interactions were significant ($P > 0.05$).

### 3.2 Body size and body condition

*R. everetti* males ($\overline{x} = 210.56 \text{ mm} \pm 1.73 \text{ SE}$) were larger than females ($\overline{x} = 200.21 \text{ mm} \pm 1.80 \text{ SE}$) ($F_{1,214} = 16.969, P < 0.001$). The removal of *R. everetti* had no significant effect on the body size of *R. everetti* during the study ($F_{1,214} = 0.204, P = 0.652$) and there was no significant difference between months ($F_{5,214} = 0.435, P = 0.824$; Figure 2).

Body mass corrected for body size was measured as an index of body condition. The mean body mass of adult *R. everetti* in the treatment and non-treatment sites was $2.9\% \ (\pm 1.4 \text{ SE})$ and $4.0\% \ (\pm 1.4 \text{ SE})$ below the mean predicted body mass in relation to their body size $^{37}$, respectively. Overall, males ($-1.0\% \pm 1.3 \text{ SE}$) were in better condition than females ($-6.8\% \pm 1.5 \text{ SE}$) ($F_{1,193} = 7.208, P = 0.008$), but the removal of *R. everetti* had no significant effect on mean adult body condition of *R. everetti* ($F_{1,193} = 0.237, P = 0.627$) and there was no significant difference between months ($F_{5,193} = 1.490, P = 0.195$).

Adult *R. tanezumi* were larger in the treatment sites than in the non-treatment sites at the start and at the end of the study period ($F_{5,115} = 3.575, P = 0.005$). The largest difference between treatments, occurred during October, when the mean adult body length of *R. tanezumi* in the treatment sites was $196.33 \text{ mm} \ (\pm 6.17 \text{ SE})$, compared to a mean body length of $166.14 \text{ mm} \ (\pm 6.08 \text{ SE})$ in the non-treatment sites.
In the treatment and non-treatment sites, the mean body condition of adult *R. tanezumi* was 5.4 % (± 1.7 SE) and 5.3 % (± 1.9 SE) below the mean predicted body mass, respectively. The removal of *R. everetti* had no significant effect on mean adult body condition of *R. tanezumi* (F\(_{1,110}\) = 0.977, P = 0.325) and there was no significant difference between months (F\(_{5,110}\) = 0.419, P = 0.835) or sex (F\(_{1,110}\) = 1.479, P = 0.2226).

Adult *C. mindorensis* males (\(\bar{x} = 172.6\) mm ± 1.84 SE) were larger than females (\(\bar{x} = 161.6\) mm ± 2.51 SE) throughout the study (F\(_{1,80}\) = 15.636, P < 0.001). The mean head and body length of adult *C. mindorensis* was substantially smaller in the treatment sites before removal of *R. everetti* in May, whereas there was little difference in size between treatments following removal of *R. everetti* (F\(_{5,80}\) = 2.461, P = 0.040).

There was a significant interaction between treatment, month and sex in relation to mean adult body condition of *C. mindorensis* (F\(_{3,64}\) = 3.954, P = 0.012). During May, all sexes were above mean body condition for both treatments. However, from July to October, *C. mindorensis* females were 20 - 26 % below the mean condition in the treatment sites, whereas in the non-treatment sites, females were above the mean condition during the same period. From June to October, mean male body condition of *C. mindorensis* fluctuated within ± 10 % of the mean predicted body mass for both treatments, with no clear pattern.

### 3.3 Sex ratio

There was a significant difference in the proportion of females trapped between species (F\(_{2,45}\) = 21.268, P < 0.001). The sex ratio of *R. tanezumi* (0.25 ± 0.03 SE) and *C. mindorensis* (0.20 ± 0.04 SE) were either close to even or male biased throughout the study, whereas the sex ratio of *R. everetti* (0.50 ± 0.03 SE) was female biased during July and August (F\(_{10,28}\) = 2.850, P = 0.014). There was a significant treatment x month interaction (F\(_{5,28}\) = 5.903, P = 0.001). In the treatment
sites, the sex ratio was female biased during August, following two months of *R. everetti* removal, and close to even or male biased at other times, whereas in the non-treatment sites the sex ratio was male biased throughout the study, aside from July when it was close to even.

3.4 Reproductive parameters

Following the removal of *R. everetti*, a lower proportion of adult *R. everetti* females were in breeding condition in the treatment sites during the post-removal period from June to October (\(\bar{x} = 24.2 \% \pm 1.88 \text{ SE}, n = 30 \text{ females}\)) than during the pre-removal period of May (\(\bar{x} = 62.5 \% \pm 2.24 \text{ SE}, n = 8 \text{ females}\)). Whereas, in the non-treatment sites, breeding condition was similar between the post-removal period (\(\bar{x} = 36.7 \% \pm 4.97 \text{ SE}, n = 43 \text{ females}\)) and the pre-removal period (\(\bar{x} = 40.0 \% \pm 8.94 \text{ SE}, n = 15 \text{ females}\)). Treatment and trapping period were significant predictors of *R. everetti* female breeding condition (Wald \(\chi^2 = 7.609, \text{ df} = 1, P = 0.006\); Wald \(\chi^2 = 3.895, \text{ df} = 1, P = 0.048\), respectively), but the treatment x trapping period interaction was not significant (Wald \(\chi^2 = 2.657, \text{ df} = 4, P = 0.103\)). This is likely due to the small sample size in May.

During the post-removal period, a higher proportion of adult *R. tanezumi* females were in breeding condition in the treatment sites (\(\bar{x} = 77.8 \% \pm 3.56 \text{ SE}, n = 11 \text{ females}\)) than in the non-treatment sites (\(\bar{x} = 26.7 \% \pm 1.83 \text{ SE}, n = 11 \text{ females}\)). However, there was no significant difference between treatments (Wald \(\chi^2 = 0.000, \text{ df} = 1, P = 1.000\)) or trapping periods (Wald \(\chi^2 = 0.580, \text{ df} = 1, P = 0.446\)), with no significant interactions (\(P > 0.05\)). The stage of the nearby rice crop also had no significant effect on the reproductive status of adult females (Wald \(\chi^2 = 3.240, \text{ df} = 4, P = 0.519\)).
A higher number of adult \textit{C. mindorensis} females were trapped in the non-treatment sites (20) than in the treatment sites (8). However, there was little difference in the proportion of adult females in breeding condition (60 \% and 50 \%, respectively). Too few adult \textit{C. mindorensis} females were trapped for meaningful analysis.

3.5 Microhabitat use

In the non-treatment sites, \textit{R. tanezumi} were more frequently trapped in trap stations with more ground vegetation cover and a similar trend was observed in the treatment sites during May (pre-removal) (Figure 3). However, following the removal of \textit{R. everetti} (June to October), \textit{R. tanezumi} microhabitat selection in the treatment sites became random with respect to ground vegetation cover, as demonstrated by a significant third order interaction (Table 3).

Across both treatments, there was a negative association between \textit{R. tanezumi} presence and increasing canopy cover (Table 3; Figure 3). On the other hand, there was a positive association between \textit{R. everetti} presence and increasing canopy cover. The probability for \textit{R. everetti} capture also increased in microhabitat with more understorey vegetation cover, but with less ground vegetation cover. However, these relationships were not significant (Table 3). The probability for \textit{R. everetti} capture was lower in the treatment sites than in the non-treatment sites, but it declined across both treatments following the removal of \textit{R. everetti} (Table 3).

The vegetation height above trap stations was not a significant factor influencing \textit{R. everetti}, \textit{R. tanezumi} or \textit{C. mindorensis} distribution in agroforest habitat ($F_{3,1473} = 0.743$, $P = 0.526$).
4 Discussion

4.1 Response of *R. everetti* following short-term control

In agroforest habitat, mark-recapture analysis indicates that a high proportion of the resident population of *R. everetti* were removed during each removal trapping session. However, during the three-week period between trapping sessions, there was rapid immigration of *R. everetti* individuals into the removal sites, possibly in response to the increased resource availability. Similar observations have been made for other small mammals following removal, where dominant species are often the first species to respond to changes in resource levels.\(^7,\,43-45\) In this case, this indicates a strong element of intraspecific competition.\(^45\) Aside from August, when the *R. everetti* sex ratio was female-biased in the treatment sites, the sex ratio did not differ between treatments, indicating that both sexes were equally prone to migration.

Even though immigration was apparent, the *R. everetti* population size in the treatment sites was lower from June to August, during the months that immediately followed removal trapping, than in May, at the start of the experiment. Coincidentally, there also was a drop in the population size of *R. everetti* in the non-treatment sites during this time. This indicates that the decrease in population size may be related to indirect factors, such as climate or food. By the end of the experiment, three months after removal trapping, the *R. everetti* population size had recovered to pre-treatment levels.

At the end of the study, few *R. everetti* individuals that had not been previously caught were trapped using kill-trapping. This supports findings from Huggins closed captures models in this study and in previous studies (see Stuart\(^37\)) showing that the capture rates of *R. everetti* using live-traps is high. In contrast, the kill-trapping results indicate that live-trapping of *R. tanezumi*
populations only appeared to trap a subset of the population, which is consistent with previous studies.\textsuperscript{37}

4.2 Response of the rodent community following the short-term removal of \textit{R. everetti}

As a consequence of rapid immigration following perturbation, \textit{R. everetti} may have been able to maintain its competitive effect over the other rodent species. If so, then the population response of the other rodent species following the removal of \textit{R. everetti} would be expected to be limited. In the treatment sites, the abundance of the other rodent species did not significantly increase following the removal of \textit{R. everetti} and rodent abundance did not differ significantly between treatments. However, there were some differences in the demographic characteristics of \textit{R. tanezumi} and \textit{C. mindorensis} between treatments.

4.2.1 \textit{Rattus tanezumi}

During the post-treatment trapping sessions, from June to October, a higher proportion of \textit{R. tanezumi} females were in breeding condition in the treatment sites than in the non-treatment sites, which suggests that \textit{R. everetti} has a negative effect on female \textit{R. tanezumi} reproductive activity in the non-treatment sites. However, due to the low numbers of \textit{R. tanezumi} females captured, there was no significant difference between treatments.

Adult \textit{R. tanezumi} were substantially larger in the treatment sites than in the non-treatment sites at the end of the study period, which suggests that three months after removal trapping, \textit{R. tanezumi} were on average older in the treatment sites.\textsuperscript{46} This may be indicative of higher survival rates, or it may be a consequence of lower recruitment rates. It is unlikely to be the latter as the proportion of females in breeding condition was higher in the treatment sites. Unfortunately, \textit{R.}
tanezumi recapture rates were too low for in-depth survival analysis using mark recapture methods. There also was no apparent difference in individual fitness between treatments, as assessed by body condition.

4.2.2 Chrotomys mindorensis

There is no evidence of direct competition between C. mindorensis and R. everetti. On the contrary, C. mindorensis females had below-average fitness values in the removal sites following the removal of R. everetti. This may the result of an indirect interaction, for example, if there was reduced competitive pressure on R. tanezumi by R. everetti in the treatment sites, this may have resulted in increased competition between R. tanezumi and C. mindorensis. Further studies, ideally over a long-term, are required to understand the importance and nature of such indirect effects.47

4.3 Microhabitat use

Following the removal of R. everetti individuals, the microhabitat selection of R. tanezumi, as measured through trap occupancy, shifted from selection towards microhabitat with more ground vegetation cover to that of no particular selection pattern, indicating that there was possibly reduced competitive pressure by R. everetti. R. everetti removal had no significant effect on R. everetti abundance, thus it is unlikely that exploitation competition between R. tanezumi and R. everetti for food patches is occurring. It seems more likely that there may be interference competition between these two species, with the larger R. everetti competitively dominant over R. tanezumi. In support of this hypothesis, previous studies on rodents have shown that female territorial defense increases during the breeding season.48,49 In this study, the lower proportion of R. everetti females in breeding condition following removal sessions suggest that these recent
immigrants were perhaps less territorial than those already established in the more stable non-treatment sites.

Irrespective of the treatment, there was a contrast in the use of canopy cover by *R. tanezumi* and *R. everetti*. *R. tanezumi* selected microhabitat with less canopy cover, which one would associate with severely disturbed habitat patches that have few trees, whereas *R. everetti* selected microhabitat with a more dense canopy. These results are consistent with the results from a radio tracking study by Stuart et al.\textsuperscript{50}, which revealed that *R. tanezumi* prefer to nest in edge or open habitat with low canopy cover. Another trapping study in the same geographical location caught few *R. everetti* in the more disturbed lowland coconut groves that have a relatively low canopy cover due to low tree species diversity, whereas trap success was higher in the agroforest and forest habitats that had denser canopy.\textsuperscript{17, 25} The differential use of microhabitat may help to explain how both of these generalist rodent species are able to co-exist in moderately disturbed agroforest ecosystems that have a heterogeneous vegetation structure.

Ong and Rickart\textsuperscript{9} postulated that practices that minimise habitat disturbance on crop margins and encourage the regeneration of second-growth forest would increase native small mammal diversity, and subsequently provide effective management against non-native pest rodents when used in conjunction with traditional control measures. Although, our study does not provide clear evidence for competition between native and invasive rodent species, the results from our study and from previous studies do indicate that the practices that minimise habitat disturbance, resulting in an increase in canopy cover, would reduce the habitat suitability for *R. tanezumi*, as well as increase the habitat suitability for *R. everetti* and other native rodent species.\textsuperscript{9, 14, 15} We hypothesise that in this type of vegetation structure there would be a decrease in the abundance of *R. tanezumi*, and a concomitant reduction in rodent losses to rice and coconut crops.
5 Conclusions

In response to the increased availability of resources following perturbation, the rapid immigration of *R. everetti* into vacated habitat indicates that this species would be able to recover from the non-target effects of short-term lethal rodent control in and around agroforest habitat. The close proximity of the removal sites to secondary lowland forest (within 200 - 500 m) may have aided the rapid immigration of this species into the treatment sites. The demographic characteristics of this species do not differ significantly between agroforest and forest habitat,\(^{37}\) even so, the complexity of the ecosystem and the level of disturbance in adjacent areas should be considered when applying lethal rodent control measures in and around agroforest habitat.

Due to the rapid immigration of *R. everetti* following removal, we were not able to fully investigate the competitive interaction between *R. everetti* and *R. tanezumi* in an agroforest habitat. To further explore this relationship, a press experiment should be designed to maintain a predetermined perturbation level by increasing the removal area with more frequent removal trapping,\(^{28}\) by adding inter-session trapping,\(^{7}\) or by continuous removal trapping throughout the removal period.

The difference in the use of vegetation cover between *R. everetti* and *R. tanezumi* provides a potential opportunity to manage the negative impact of an invasive pest species on agricultural crops by minimising disturbance and allowing more natural habitat to regenerate within agroforest, particularly around crop margins. We would expect this to be beneficial to other native flora and fauna, as well as favour the native rodent *R. everetti* over the invasive rodent *R. tanezumi*. This could provide a novel approach to species conservation in agro-ecosystems that may also benefit small-scale farmers; providing a balance between human needs and conservation.
that is often required to protect fragile ecosystems on a landscape scale.\textsuperscript{51} Replicated habitat manipulation studies are now needed to test this approach in the field.

**Acknowledgements**

We thank Dr. L. Sebastian, Dr. R. Joshi and the Crop Protection staff from the Department of Agriculture-Philippine Rice Research Institute (DA-PhilRice) for their support in setting up the project. AMS thanks R. Gadayan for his dedicated assistance in the field; P. Leander, O. Diesta and A. Novicio for helping to establish contacts within the local communities; B. Mina and M. Millan for their assistance in the acquisition of scientific permits; and the local farmers for permitting to trap on their land. We gratefully acknowledge Prof. C. Krebs for advice on experimental design; and Dr. P. Baker for his statistical advice. We thank anonymous reviewers for their helpful comments that improved the manuscript. Fieldwork was approved by the municipal governments of Baler and San Luis and scientific permits were granted by the Philippine Department of Environment and Natural Resources (07-13488/062507). The project was supported by funding to the International Rice Research Institute provided by the Swiss Agency for Development and Cooperation for the Irrigated Rice Research Consortium.
