ABSTRACT

The co-polar correlation coefficient ($\rho_{hv}$) has many applications, including hydrometeor classification, ground clutter and melting layer identification, interpretation of ice microphysics and the retrieval of rain drop size distributions (DSDs). However, we currently lack the quantitative error estimates that are necessary if these applications are to be fully exploited. Previous error estimates of $\rho_{hv}$ rely on knowledge of the unknown ‘true’ $\rho_{hv}$ and implicitly assume a Gaussian probability distribution function of $\rho_{hv}$ samples. We show that frequency distributions of $\rho_{hv}$ estimates are in fact highly negatively skewed. A new variable: $L = -\log_{10}(1 - \rho_{hv})$ is defined, which does have Gaussian error statistics, and a standard deviation depending only on the number of independent radar pulses. This is verified using observations of spherical drizzle drops, allowing, for the first time, the construction of rigorous confidence intervals in estimates of $\rho_{hv}$. In addition, we demonstrate how the imperfect co-location of the horizontal and vertical polarisation sample volumes may be accounted for.

The possibility of using $L$ to estimate the dispersion parameter ($\mu$) in the gamma drop size distribution is investigated. We find that including drop oscillations is essential for this application, otherwise there could be biases in retrieved $\mu$ of up to $\approx 8$. Preliminary results in rainfall are presented. In a convective rain case study, our estimates show $\mu$ to be substantially larger than 0 (an exponential DSD). In this particular rain event, rain rate would be overestimated by up to 50% if a simple exponential DSD is assumed.
1. Introduction

The co-polar correlation coefficient, $\rho_{hv}$, between horizontal ($H$) and vertical ($V$) polarisation radar signals is a measure of the variety of hydrometeor shapes in a pulse volume. It is therefore useful for applications such as identifying the melting layer (Caylor and Illingworth 1989; Brandes and Ikeda 2004; Tabary et al. 2006; Giangrande et al. 2008), ground clutter (e.g. Tang et al. 2014), rain-hail mixtures (Balakrishnan and Zrnic 1990) and interpreting polarimetric signatures in ice (e.g. Andrić et al. 2013), and potentially the retrieval of the drop size distribution (DSD). The standard deviations of differential reflectivity ($Z_{DR}$) and differential phase shift ($\phi_{dp}$) are both functions of $\rho_{hv}$ (Bringi and Chandrasekar 2001). Therefore, $\rho_{hv}$ dictates both the quality of dual polarisation measurements and their weighting in hydrometeor classification schemes (Park et al. 2009). In rainfall, $\rho_{hv}$ is typically 0.98—1. Giangrande et al. (2008) use data where $\rho_{hv} < 0.97$ to identify the melting layer. For hail, $\rho_{hv}$ can be much lower due to the effects of Mie scattering. At present, quantitative use of $\rho_{hv}$ is hampered by a lack of rigorous confidence intervals accompanying the $\rho_{hv}$ estimates. Error estimates are available adopting an empirical approach (Illingworth and Caylor 1991) or a linear perturbation technique (Liu et al. 1994; Torlaschi and Gingras 2003), both of which implicitly assume a Gaussian probability distribution for the $\rho_{hv}$ samples. We will show that the distribution of $\rho_{hv}$ samples is in fact non-Gaussian and highly negatively skewed.

Natural rain drop size distributions can be described by a gamma distribution (Ulbrich 1983):

$$N(D) = N_0 D^\mu \exp \left[ -\frac{(3.67 + \mu)}{D_0} D \right]$$

where $D$ is the equivalent spherical drop diameter, $N_0$ is the intercept parameter, $D_0$ is the median volume drop diameter and $\mu$ is the dispersion parameter (a measure of the drop size spectrum shape). If $\mu = 0$, by exploiting the relationship between drop diameter and drop
axis ratio, $D_0$ can be estimated using $Z_{DR}$ (Seliga and Bringi 1976). Higher $\mu$ correspond to more monodisperse drop size distributions. Since $\rho_{hv}$ is sensitive to variations in drop shape, it can in principle be used to estimate $\mu$ (Jameson 1987), knowledge of which could improve dual polarisation and dual frequency (e.g. the Global Precipitation Measurement satellite) rain rate estimates. Figure 1 shows rain rate ($R$) per unit radar reflectivity ($Z$) as a function of $Z_{DR}$ for simulated Gamma distributions with $\mu = -1, 0, 2, 4, 8, 12$ and $16$. The rain rate is sensitive to variability in the shape of the drop size spectrum; uncertainty in $\mu$ alone could introduce an error in the retrieved rain rate of up to 2.5 dB (almost a factor of 2) for a given pair of $Z$ and $Z_{DR}$ observations.

It is difficult to obtain reliable estimates of $\mu$ from observations. Disdrometers suffer from undersampling of large drops, which cause $\mu$ values that are derived from the 3rd, 4th and 6th moments of the drop size distribution to be biased high (Johnson et al. 2014). Furthermore, disdrometers also undercount the number of drops < 0.5 mm (Tokay et al. 2001), which can also introduce a bias in estimates of $\mu$. Estimating DSD parameters using radar is therefore preferable, due to the very large number of drops being sampled. Wilson et al. (1997) made radar observations dwelling in rain at elevation angles above 20° and report that the difference in the mean Doppler velocity at $H$ and $V$ polarisations provides an estimate of $\mu$, which were in the range of 1 to 11, and, once $Z_{DR}$ exceeded 0.5 dB, all the values were above 4. Doppler spectra of rain at vertical incidence with multiple wavelength radars, including wind profiler frequencies that respond to the clear air motion have been utilised to estimate $\mu$ (Williams 2002; Schafer et al. 2002). These experiments find $\mu$ ranges between 0 and 18, but is typically 0—6. Unal (2015) fits observed Doppler spectra to theoretical drop spectra at S-band, and retrieves $\mu$ in the range of -1—5. The disadvantage of these techniques is that they use high elevation angles; for operational monitoring of surface rainfall, measurements at low elevation angles are preferable. This motivates the use of $\rho_{hv}$ to derive $\mu$ in rainfall. Illingworth and Caylor (1991) and Thurai et al. (2008) inferred $\mu$ from the decrease in $\rho_{hv}$ as $Z_{DR}$ increases. The difficulty here is that any mis-matches in the $H$ and $V$ beams
will introduce an uncorrelated noise component, so that even for perfectly spherical drizzle
droplets, where the “true” $\rho_{hv}$ is unity, the radar will always detect a value less than one (we
will call this maximum obtainable level of $\rho_{hv}$ as $f_{hv}^{max}$, see Section 5). From measurements in
rain at short range, Illingworth and Caylor (1991) inferred $\mu$ values, which if corrected with
an estimate of $f_{hv}^{max}$ were in the range 0—2, but even for long dwells the estimated errors
in $\mu$ were quite large. Thurai et al. (2008) analysed $\rho_{hv}$ measurements from an operational
radar and obtained estimates of $\mu$ in the range of 1—3, however their approach relies on
empirically derived relationships between $\rho_{hv}$ and DSD widths from 2 dimensional video
disdrometer (2DVD) measurements. Furthermore, the technique is only valid for intense
rain ($Z_{DR} \geq 2$ dB and $\rho_{hv} < 0.98$).

The aim of this paper is to define a new variable, $L = -\log_{10}(1 - \rho_{hv})$, that has Gaussian
error statistics with a width predictable from the number of independent radar pulses. This
can be readily estimated by using the observed Doppler spectral width ($\sigma_v$). We will then
present measurements of $L$ in rainfall as a function of $Z_{DR}$, and retrieve estimates of $\mu$ by
comparing these with predicted $L$ and $Z_{DR}$ for various three-parameter gamma distributions.
The possibility of using this technique to retrieve $\mu$ using operational radars is then discussed.

### 2. The Co-Polar Correlation Coefficient ($\rho_{hv}$)

$\rho_{hv}$ is defined as (Doviak and Zrnic 2006):

$$
\rho_{hv} = \frac{\langle S_{VV} \cdot S_{HH}^* \rangle}{\sqrt{\langle |S_{HH}|^2 \rangle \langle |S_{VV}|^2 \rangle}}
$$

(2)

where $\langle S_{HH} \rangle$ and $\langle S_{VV} \rangle$ are the co-polar elements of the backscattering matrix averaged
over an ensemble of scatterers for the H and V polarisations respectively, and $^*$ indicates the
complex conjugate. It can be estimated by correlating successive power or complex ($I$ and
$Q$) measurements. Examples of power time-series in (a) drizzle and (b) heavier rainfall from
the 3 GHz Chilbolton Advanced Meteorological Radar (CAMRa) are shown in figure 2. The radar is a coherent-on-receive magnetron system, transmitting and receiving alternate H and V polarised pulses with a pulse repetition frequency (PRF) of 610 Hz. A cubic polynomial interpolation is used to estimate the H power at the V pulse timing and the V power at the H pulse timing. Its narrow one-way half power beamwidth (0.28°) makes it capable of very high resolution measurements. The full capabilities of this radar are discussed in Goddard et al. (1994). The observed fluctuating signals in Figure 2 are caused by the superposition of the backscattered waves from each drop in the sample volume; the rate of fluctuation is determined by the Doppler spectral width. For drizzle, since the drops are spherical, $Z_{DR} = 0$ dB, and the H and V signals are almost perfectly correlated: $\rho_{hv} = 0.995$. For heavier rainfall, a systematically lower V power is received ($Z_{DR} = 1.1$ dB), and the signals are visibly less correlated ($\rho_{hv} = 0.987$), due to the broader axis ratio distributions in the sample volume.

These estimates of $\rho_{hv}$ are derived from a finite number of reshufflings, and therefore there is some uncertainty in them. In what follows, we quantify this uncertainty.

3. Theoretical Measurement Error in Estimated Correlation of Time-Series

Figure 3a shows the distribution of estimates of the correlation coefficient, $\hat{\rho}_{hv}$ (calculated from a finite length time-series), as distinct from the “true” co-polar correlation coefficient, $\overline{\rho}_{hv}$ (that would be measured for a time-series of infinite length). The data was collected during a 1.5° elevation dwell in drizzle ($Z_{DR} < 0.1$ dB), with very high SNR (> 40 dB) on 6 February 2014. Each $\hat{\rho}_{hv}$ is calculated from 64 H and V pulse pairs (0.21s dwell) from a single 75 m range gate with $\sigma_v = 1.1 \pm 0.1$ ms$^{-1}$. The distribution of $\hat{\rho}_{hv}$ has a peak that is close to $\overline{\rho}_{hv}$ (which is < 1, see Section 5d), but exhibits a very long tail at lower $\hat{\rho}_{hv}$, while there are no data with $\hat{\rho}_{hv} > 1$. Clearly, this distribution is not Gaussian and the negative
skewness will negatively bias the mean of many $\hat{\rho}_{hv}$ samples compared to the true value of $\rho_{hv}$.

Fisher (1915) states that sample correlation coefficients ($\hat{\rho}$) of a “true” correlation coefficient ($\bar{\rho}$) calculated from a finite number of Gaussian random variables are skewed for $\bar{\rho} \neq 0$. However, the variable:

$$\hat{F} = \frac{1}{2} \ln \left( \frac{1 + \hat{\rho}}{1 - \hat{\rho}} \right)$$

is Gaussian, with a mean of:

$$F = \frac{1}{2} \ln \left( \frac{1 + \bar{\rho}}{1 - \bar{\rho}} \right)$$

and standard error of:

$$\sigma_F = \frac{1}{\sqrt{N - 3}}$$

where $N$ is the number of independent samples used to calculate $\hat{\rho}$.

This is directly applicable to estimates of the radar co-polar correlation coefficient, by realising that the $I$ and $Q$ samples that are used to estimate $\rho_{hv}$ are Gaussian random variables (Doviak and Zrnic 2006). Noting that $\rho_{hv}$ in meteorological targets is always close to unity so that fractional changes in $(1 - \hat{\rho}_{hv})$ are always much greater than $(1 + \hat{\rho}_{hv})$, Equation 3 can be written as:

$$\hat{F} \approx \frac{1}{2} \ln 2 - \frac{\ln 10}{2} \log_{10}(1 - \hat{\rho}_{hv})$$

Since $\hat{F}$ is normally distributed, the quantity:

$$\hat{L} = - \log_{10}(1 - \hat{\rho}_{hv})$$

is also normally distributed, with a mean:
\[ \bar{L} = -\log_{10}(1 - \hat{\rho}_{hv}) \]  
(8)

and standard deviation of:

\[ \sigma_L = \frac{2}{\ln 10} \times \frac{1}{\sqrt{N_{IQ} - 3}} \]  
(9)

for \( N_{IQ} \gg 3 \), where \( N_{IQ} \) is the number of independent \( I \) and \( Q \) samples used to calculate \( \hat{\rho}_{hv} \). Despite having similar characteristics, \( L \) is preferred over the use of \( F \) as it has the convenient property that \( \rho_{hv} = 0.9, 0.99 \) and \( 0.999 \) correspond to \( L = 1, 2 \) and \( 3 \) respectively and therefore is more intuitive. Illingworth and Caylor (1991) plotted their \( \hat{\rho}_{hv} \) data as \( \log_{10}(1 - \hat{\rho}_{hv}) \) and their histograms also appear Gaussian in shape. Figure 3b illustrates the effect of the transform \( \hat{L} = -\log_{10}(1 - \hat{\rho}_{hv}) \) on the distribution in Figure 3a. The histogram is now symmetrical, and bell shaped. A Gaussian curve with an equal mean and standard deviation to the \( \hat{L} \) PDF is overplotted and is an excellent fit to the data, showing that the distributions are indeed Gaussian (and Quantile - Quantile plots, not shown here for brevity, confirm this).

To determine the number of independent \( I \) and \( Q \) samples, \( N_{IQ} \), we consider the autocorrelation function for \( I \) and \( Q \) samples given by Doviak and Zrnic (2006):

\[ R_{IQ}(nT_s) = \exp \left[ -8 \left( \frac{\pi \sigma_v nT_s}{\lambda} \right)^2 \right] \]  
(10)

where \( T_s \) is the time spacing between pulses of the same polarisation and \( nT_s \) is the total time lag. Following the definition of Papoulis (1965), the time to independence for \( I \) and \( Q \) samples for large \( N_{IQ} \) can be shown to be:

\[ \tau_{IQ} = \frac{\lambda}{2\sqrt{2\pi}\sigma_v} \]  
(11)

where \( \lambda \) is the radar wavelength and \( \sigma_v \) is the Doppler spectral width. This is a factor of \( \sqrt{2} \) smaller than the more often used time to independence for reflectivity samples. The number
of independent $I$ and $Q$ pulses per $\rho_{hv}$ sample can therefore be estimated by:

$$N_{IQ} = \frac{T_{dwell}}{\tau_{IQ}} = \frac{2\sqrt{2\pi\sigma_v T_{dwell}}}{\lambda}$$

(12)

where $T_{dwell}$ is the dwell time.

The result (Equation 9) is significant as it shows that a confidence interval for any measurement of $\rho_{hv}$ can be calculated solely in terms of the number of independent $I$ and $Q$ samples used to estimate it, which in turn can be readily estimated using the observed Doppler spectral width and Equation 12. Furthermore, when multiple samples of $\hat{L}$ are averaged, no bias is introduced to estimates of $\rho_{hv}$ because of the non-linear transform. We expand this point in Section 4.

To estimate confidence intervals for measurements of $\rho_{hv}$, one must:

- Apply the transform $\hat{L} = -\log_{10}(1 - \hat{\rho}_{hv})$
- Calculate the standard deviation of $\hat{L}$ using Equation 9.
- Apply the inverse transform $1 - 10^{-(\hat{L} \pm \sigma_{L})}$ to obtain upper and lower confidence intervals (where $\sigma_{L}$ will contain the true value 68% of the time and $2\sigma_{L}$ 98%).

More conveniently, one can simply transform $\hat{\rho}_{hv}$ data to $\hat{L}$ and use this for any subsequent analysis, with confidence intervals of $\hat{L} \pm \sigma_{L}$. This is the approach we follow in the rest of this paper. Although we are focusing on data with very high signal-to-noise (SNR) in this paper, the theory above should also be valid for weak SNR data, providing that noise introduced is also Gaussian in the $I$ and $Q$ samples.

This theoretical prediction was tested by comparing estimates of $\sigma_{L}$ using data collected in homogeneous drizzle ($Z_{DR} < 0.1$ dB) with very good signal-to-noise (SNR $> 40$ dB). In drizzle, $\overline{L}$ is constant since the drops are spherical, and therefore any variation $\sigma_{L}$ is due to the finite $N_{IQ}$. Pulse-to-pulse $H$ and $V$ powers were recorded, and time series of various lengths between 0.2—30 s were constructed from these data and used to compute
the corresponding \( N_{IQ} \) and \( L \) values. Data was binned by \( N_{IQ} \), and the standard deviation, \( \sigma_L \), were computed for each bin. Figure 4 shows how \( \sigma_L \) decreases as \( N_{IQ} \) is increased over more than two orders of magnitude. \( \sigma_L \) is slightly overestimated for \( N_{IQ} \approx 10 \), and the data is in excellent agreement to that predicted by Equation 9 for \( N_{IQ} > 30 \).

### 4. Comparison with Existing Error Statistics

We now compare these new error statistics with existing methods in the literature. From observations of \( \rho_{hv} \) in rain, the bright-band and ice, Illingworth and Caylor (1991) derived empirically the relationship between their mean \( \hat{\rho}_{hv} \) estimates and their standard deviation:

\[
\sigma^{IC}_{\rho_{hv}} \approx \frac{1.25(1 - \hat{\rho}_{hv})}{\sqrt{n}} \tag{13}
\]

where \( n \) is the number of 0.2 s time-series they used to estimate the mean \( \rho_{hv} \). Using a linear perturbation technique, Torlaschi and Gingras (2003) derive the following equation for the standard deviation on a \( \rho_{hv} \) measurement:

\[
\sigma^{TG}_{\rho_{hv}} = \frac{1 - \bar{\rho}_{hv}^2}{\sqrt{2N_I}} \tag{14}
\]

where \( N_I \) is the number of independent radar reflectivity samples used in its estimation. Note that \( \bar{\rho}_{hv} \) in Equation 14 is the “true” correlation coefficient one is attempting to measure (rather than the measured value, \( \hat{\rho}_{hv} \)). This equation represents the standard deviation for infinite SNR conditions, and is valid for simultaneous or accurately interpolated \( H \) and \( V \) sampling. Neither of these techniques are ideal, relying on either knowing a-priori the true correlation coefficient one is attempting to measure (Torlaschi and Gingras 2003), or a number of time-series (Illingworth and Caylor 1991), not the number of independent pulses. It is not possible to compare the method of Illingworth and Caylor (1991) with our proposed method as \( \sigma_v \) for their data is unknown, and therefore the number of independent pulses in their time-series cannot be quantified. Figure 5a shows the errors on \( \hat{\rho}_{hv} \) calculated using our
new method compared to those calculated using the linear perturbation method of Torlaschi and Gingras (2003) as a function of \( N_{IQ} \) in rain \((\overline{\rho_{hv}} = 0.98)\). The magnitudes of the upper confidence bounds are largely similar, however, for all \( N_{IQ} \) the lower confidence interval is higher for Torlaschi and Gingras (2003) (i.e smaller deviations from \( \overline{\rho_{hv}} \) are predicted), due to the asymmetric nature of the new confidence intervals on \( \hat{\rho}_{hv} \). The largest difference is for small \( N_{IQ} \). As \( N_{IQ} \) increases, both the upper and lower confidence intervals for each method converge. Although Figure 5a serves as a useful illustration of the difference between the methods, they are not strictly comparable in practice: the error calculation of Torlaschi and Gingras (2003) relies on knowledge of \( \rho_{hv} \) which in reality is unknown. Conversely, the new method requires no a-priori knowledge of \( \overline{\rho_{hv}} \), and so is of much greater practical use.

Figure 5b illustrates the theoretical bias introduced by averaging many short samples of \( \hat{\rho}_{hv} \), rather than \( \hat{L} \), in rain \((\overline{\rho_{hv}} = 0.98)\). This bias is significant for small \( N_{IQ} \). For example, when \( N_{IQ} = 10 \), the bias on \( \hat{L} \) is 0.1, which is significant for the purpose of estimating \( \mu \) in rainfall; this bias in \( L \) could lead to an underestimate of \( \mu \) of \( \approx 8 \) at \( Z_{DR} = 2 \) dB (see figure 8). It is not important whether spatial or temporal averaging is used to increase the number of independent \( I \) and \( Q \) samples, as long as \( \overline{\rho_{hv}} \) does not vary substantially over the scales considered.

In summary, confidence intervals that rely on the linear perturbation method overestimate the precision of \( \rho_{hv} \) measurements, and require knowledge of the “true” \( \rho_{hv} \) one is attempting to measure. Fundamentally, failure to use the transform \( L \) when averaging short time-series will lead to significant biases in correlation coefficient estimates. This is particularly important for operational \( \rho_{hv} \) applications that typically use very short dwell times (discussed in Section 8a), and would lead to a significant bias in retrievals of \( \mu \) in rain.
5. Practical measurement of $\rho_{hv}$

To fully exploit our new error estimates, and retrieve rain DSDs, some practical considerations for the measurement of $\rho_{hv}$ must first be considered.

a. Effect of alternate sampling

When estimating the correlation coefficient, the non-simultaneous transmission and reception of $H$ and $V$ pulses must be accounted for. Assuming a Gaussian autocorrelation function to correct for this staggered sampling (Sachidananda and Zrnic 1989) can lead to unphysical samples where $\hat{\rho}_{hv} > 1$ (Illingworth and Caylor 1991). In our analysis, we employ a cubic polynomial interpolation to obtain $H$ and $V$ power estimates at the intermediate sampling intervals (Caylor 1989), which is very effective. We find that the interpolation scheme works well: for drizzle with $\bar{L} = 2.4$, we observe that average values of $\hat{L}$, binned by $\sigma_v$, are constant to within $\pm 0.02$ as $\sigma_v$ varies between $0.1—2$ ms$^{-1}$. This is evidence of successful interpolation, since there is no systematic trend to lower $L$ values at higher spectral widths.

b. Signal-to-noise ratio

The addition of noise to the received signals acts to reduce the correlation between $H$ and $V$ time-series. The reduction factor, $f$, has been shown (Bringi et al. 1983) to vary predictably as:

$$f = \frac{1}{\left(1 + \frac{1}{\text{SNR}_H}\right)^{\frac{1}{2}} \left(1 + \frac{1}{\text{SNR}_V}\right)^{\frac{1}{2}}}$$

for simultaneous (or accurately interpolated) $H$ and $V$ sampling, where $\text{SNR}_H$ and $\text{SNR}_V$ are the signal-to-noise ratios for the $H$ and $V$ polarisations respectively. This was verified by
Illingworth and Caylor (1991) with measurements of $\rho_{hv}$ in drizzle. Whilst it is in principle possible to correct for the presence of noise using this equation, due to the high degree of precision required in this work, only data with SNR $> 34$ dB are included in our analysis, which corresponds to a maximum achievable $\rho_{hv}$ measurement of 0.9996. However, instrumental effects (described in Section d below) will have the same effect of adding uncorrelated noise, and so in practice this maximum value is never reached.

c. Effect of phase error

To avoid a bias in $\hat{\rho}_{hv}$ due to random phase error from our magnetron system (Liu et al. 1994), we cross correlate the power of the received echoes as opposed to the complex $I$ and $Q$ signals, and take the square root, following Illingworth and Caylor (1991).

d. Instrumental effects

Even in drizzle with very high SNR, antenna imperfections and other effects such as irregular magnetron pulse timing and pulse shape reproducibility will cause measured $\rho_{hv}$ to always be $< 1$ (Illingworth and Caylor 1991; Liu et al. 1994) as effectively they cause the $H$ and $V$ pulses to sample slightly different volumes. Here, we propose a method to quantify and account for this bias, analogous to the SNR factor (Equation 15) suggested by Bringi et al. (1983). We consider the $H$ and $V$ echoes to consist of two parts: a common sample volume, and parts of each sample volume which are unique to a particular polarisation. By treating the former as “signal” and the latter as unwanted “noise”, we obtain an equation similar to Equation 15. Full details are provided in the appendix. The practical upshot is that the measured $\rho_{hv}$ is the “true” $\rho_{hv}$ multiplied by some dimensionless factor, $f_{hv}^{\text{max}}$, relating to how well matched the $H$ and $V$ sample volumes are. For spherical drops, $\overline{\rho_{hv}}$ should be unity. The estimates of $\overline{\rho_{hv}}$ for all such data should therefore be equal to $f_{hv}^{\text{max}}$. When comparing observations with simulated $\rho_{hv}$, we multiply each of the predicted values...
by $f_{hv}^{\text{max}}$ so that they are directly comparable to the observations. $\rho_{hv}$ has been measured in drizzle ($Z_{DR} < 0.1$ dB) for a large number of samples on several days. Typically, $f_{hv}^{\text{max}}$ is $\approx 0.996$, but varies by $\pm 0.001$ from day to day, which we suggest is the result of slightly irregular magnetron pulse timing and shape reproducibility for the CAMRa system, which may be temperature dependent. For this reason, $f_{hv}^{\text{max}}$ has been determined individually for each case.

### 6. Using $L$ and $Z_{DR}$ to Estimate $\mu$ in Rainfall

We now attempt to use our high-precision measurements of $L$ to retrieve $\mu$ estimates in rainfall. The independence of $(D_0, \mu)$ and $(L, Z_{DR})$ on the drop number concentration means that a single $L$ and $Z_{DR}$ observation pair corresponds to a unique $D_0$ and $\mu$ value. In order to forward model $L$ and $Z_{DR}$ for various gamma distributions, we must first assume an appropriate drop shape model.

#### a. Mean Drop Shapes

There are numerous drop shape parameterisations in the literature. Here, we examine drop axis ratios and diameters from the recent experiments of Thurai and Bringi (2005), Szakáll et al. (2008) and the 4th order polynomial fit to many experiments given by Brandes et al. (2002). Figure 6a shows the mean axis ratio as a function of drop diameter, for each of these models. The Thurai and Bringi (2005) data suggests that mean drop shapes are slightly prolate for $D < 1$ mm, although it is in the margin of measurement error that the drops are spherical (Beard et al. 2010). Since it is known that drops become spherical as their diameter tends to 0 mm due to surface tension, our fit to the data is adapted so that drops $< 1$ mm are precisely spherical.

To choose the best mean drop shape model, a 5 hour dwell was made with CAMRa at a 1.5° elevation angle over a nearby Joss-Waldvogel RD-80 impact disdrometer (approximately
7 km away) in a frontal rain band on 25 April 2014. The disdrometer measures drop sizes in
127 size bins from 0.3 to 5.0 mm. The instrument is regularly calibrated by the manufacturer
and rain rate estimated with this instrument agrees very well with that from a co-located
rain gauge. Radar measurements of $Z_{DR}$ are calibrated regularly (to within ±0.1 dB) by
making observations of drizzle (low $Z$), which we know to have a $Z_{DR}$ value of 0 dB. The
range resolution of the radar measurements is 75 m, and averaged to 30 s to match the
integration time used by the disdrometer to estimate the DSD parameters. At this elevation
angle, the radar was sampling rain at a height of 183m above the disdrometer. Figures
6b—d show the observed radar measurement from the closest gate to the disdrometer, and
the corresponding disdrometer $Z_{DR}$ values calculated using the Thurai and Bringi (2005),
Szakál et al. (2008) and Brandes et al. (2002) drop shape models respectively. The Szakál
et al. (2008) axis ratios are systematically smaller compared to both of the other models for
almost all $D$. Using this model makes the disdrometer estimates of $Z_{DR}$ always larger than
the radar estimates. Thurai and Bringi (2005) and Brandes et al. (2002) agree for $D = 2—7$
mm, after which the axis ratios of Thurai and Bringi (2005) are closer to those of Szakál
et al. (2008). Therefore, radar and disdrometer $Z_{DR}$ for the Thurai and Bringi (2005) and
Brandes et al. (2002) models largely agree, apart from $Z_{DR} \lesssim 0.4$ dB. The largest differences
between these models occurs for $D < 2$ mm. Here, Szakál et al. (2008) and Brandes et al.

The Szakál et al. (2008) model produces the largest radar-disdrometer overall bias of
$\approx 0.23$ dB. The biases from Brandes et al. (2002) for $Z_{DR}$ bins of 0.2, 0.4 and 0.6 dB ($\pm$
0.1 dB bin width) are 0.09, 0.16 and 0.13 dB respectively. For Thurai and Bringi (2005),
they are only 0.04, 0.08 and 0.09 dB respectively, and are very similar to Brandes et al.
(2002) at higher $Z_{DR}$. These reduced biases at low $Z_{DR}$ suggest that the experimental
results of Thurai and Bringi (2005) best represent natural raindrop shapes. We therefore
chose this model in our analysis. It is unclear why the very small residual difference between
radar and disdrometer estimates of $Z_{DR}$ using the Thurai and Bringi (2005) shape model is
observed. Some possible explanations are that the radar calibration is slightly out causing a
systematic underestimation, the small sampling volume of the disdrometer could be biasing \( Z_{DR} \), or there could be residual error in the mean drop shape model. However, this very
small difference is unimportant for retrievals that follow.

\[ b. \text{ Drop Oscillations} \]

Drop oscillations increase the variety of shapes within a radar pulse volume at any given
time. This means that the \( \overline{L} \) we are attempting to estimate will be lower than that predicted
by modelling only the mean drop axis ratios for drops of a given size. In order to account
for this, we must parameterise these drop oscillations. In the Thurai and Bringi (2005)
experiment, artificial rain drops were created from a hose and allowed to fall 80 m from
a bridge before drop axis ratio and counts were measured with a 2D video disdrometer
(2DVD) on the valley floor. This fall distance is more than sufficient to allow the drops to
achieve steady state oscillations, and so the standard deviations of axis ratios measured in
this experiment are interpreted as drop oscillation amplitudes. However, the large standard
deviations of the axis ratios for \( D < 2 \text{ mm} \) are likely artificial, caused by the finite resolution
of the 2DVD instrument (Beard et al. 2010). Since drop oscillations are thought to originate
from vortex shedding (Beard et al. 2010) which increases as a function of drop size, the
magnitude of oscillations should decrease eventually to zero as the drop diameter tends to
0 mm. Beard and Kubesh (1991) suggest that resonant drop oscillations occur for drop
sizes between 1.1 and 1.6 mm, however more recent measurements from the Mainz wind
tunnel show that amplitudes of the axis ratios for these drop sizes were less than 0.025
(Szakáll et al. 2010). For this reason, the polynomial fit to oscillation amplitude data from
the Mainz wind tunnel (Szakáll et al. 2010) is used for \( D < 2 \text{ mm} \), which has the desired
reduction in oscillation amplitude for small drops \(^1\). For \( D > 2 \text{ mm} \), we revert to the more

\(^1\)Equation 1 in Szakáll et al. (2010) does not agree with the fit in Figure 3 (black line). By digitising the
Mainz wind tunnel data, we calculate that Equation 1 should in fact be \( 1.8 \times 10^{-3}D_0^2 + 1.07 \times 10^{-2}D_0 \)
statistically robust drop oscillations from Thurai and Bringi (2005). Since the oscillations are aerodynamically induced, with an amplitude only a function of the drop size, they should not vary with environmental conditions. In our analysis, the oscillations were included by integrating over Gaussian PDFs of axis ratios (Thurai and Bringi 2005) in our Gans theory computations. Figure 7 shows the effect of oscillations on computed $L$ and $Z_{DR}$ for values of $\mu = -1$ (black lines), $\mu = 16$ (grey lines). Including drop oscillations for the purpose of estimating $\mu$ becomes increasingly important with increasing $Z_{DR}$; the difference between $L$ at $\mu = 16$ computed with and without oscillations is as large as an equivalent change in $\mu$ of $\approx 8$. We find that the modification of the oscillation magnitudes for drop diameters $< 2$ mm has a relatively small impact ($< 0.01$) on predicted $L$ for $Z_{DR}$ larger than 0.8 dB where we attempt retrievals of $\mu$. However, we find that the use of Szakáll et al. (2010) oscillations for all drop diameters has a large impact on predicted $L$ values (for $\mu = -1$, $L$ is $\approx 0.1$ lower). This is potentially important for retrievals of $\mu$.

Comparatively large amplitude (but short lived, lasting less than $\approx 0.4$ s) collision-induced oscillations can also occur (Szakáll et al. 2014). Rogers (1989) estimate that the collision rate for an average rain drop in a 55 dBZ rain column is $\approx 1 \text{ min}^{-1}$. This would imply that rain drops (even in very heavy rainfall) spend an almost negligible fraction of time ($\approx 0.5\%$) affected by collision-induced oscillations. Rain drop clustering increases the likelihood of these collisions (Jameson and Kostinski 1998). For rain rates of around 10 mm hr$^{-1}$ (comparable to those presented in the following case studies), McFarquhar (2004) estimate the collision rate to be $\approx 5 \text{ min}^{-1}$, implying drops are affected only 3% of the time. For very large rain rates (100 mm hr$^{-1}$), this fraction increases to 6% as the collision rate approximately doubles to 10 min$^{-1}$. Consequently, their impact on $L$ measurements is likely to be small and can be ignored, other than for exceptional rain rates (Thurai et al. 2013).

Figure 8 shows how $L$ varies as a function of $Z_{DR}$ for gamma distributions with $\mu = -1, 0, 2, 4, 8, 12$ and 16 computed using Gans theory with the drop shape and oscillation model discussed above. Note that lines of constant $\mu$ diverge with increasing $Z_{DR}$. For $Z_{DR} \gg$
0.5 dB, it becomes possible to distinguish $\mu$, given the typical error on an $L$ measurement (shown in Figure 9).

7. $\mu$ Retrieval Case Studies

We now estimate $\mu$ using measurements of $L$ and $Z_{DR}$ for stratiform rain case studies on 31 January, 25 April and 25 November 2014, and a convective case study on 22 May 2014. Typical rain rates for each of these case studies can be found in Table 1. Dwell were made at an elevation angle of 1.5°. Strict data quality filters were applied: SNR $> 34$ dB, linear depolarisation ratio (LDR) $< -27$ dB (close to the limit of cross-polar isolation) to ensure no melting particle contamination or ground clutter and range $> 5$ km to avoid near-field effects. Theoretical $L$ and $Z_{DR}$ were computed using Gans theory using the drop shape and oscillation model discussed in Section 6 (see Figure 8). Observations were averaged from 10 to 30 s and from range gates of 75 to 300 m to increase the measurement precision of $L$. At each gate, the most likely pair of $\mu$ and $D_0$ given the observed $L$ and $Z_{DR}$ values was obtained by selecting the closest point in a look-up table of Gamma DSD calculations. Figure 9a shows the observed $L$ binned every 0.02 and $Z_{DR}$ binned every 0.05 dB for the example of 25 November 2015. Overlayed are lines of constant $\mu = -1, 0, 2, 4, 8, 12$ and 16. Figure 9b is the same distribution normalised to sum to 1 for each $Z_{DR}$ bin. The $f_{hv}^{\text{max}}$ on this day was calculated to be 0.9963 (see Section 5d). The observations of $L$ and $Z_{DR}$ are generally well contained within the expected range. The median error on $\hat{L}$ is $\sigma_L \approx 0.025$, and is shown as a representative error bar in Figure 9. A comparison of these data with disdrometer measurements from Williams et al. (2014) is included. In this experiment, the mass spectrum mean diameter ($D_m$) and mass spectrum standard deviation ($\sigma_m$) were measured using a 2DVD. A $\sigma_m - D_m$ fit was derived from 18969 1-minute drop spectra (which can readily be converted to a $\mu - D_0$ fit). This was in turn used to predict a $L - Z_{DR}$ relationship, shown by the grey dashed line. $L$ and $Z_{DR}$ were also predicted using the
proposed $\mu - \Lambda$ relationship of Cao et al. (2008), also derived from a 2DVD, where:

$$\Lambda = \frac{3.67 + \mu}{D_0}$$  \hspace{1cm} (16)$$

This is shown by the black dashed line.

The median and inter-quartile range of retrieved $\mu$ per $Z_{DR}$ bin for this day is shown in Figure 10. The median retrieved $\mu$ is 5 at $Z_{DR} = 0.8$ dB, increasing to 8 for $Z_{DR} = 1.6$ dB. There is significant spread in retrieved $\mu$ values, containing contributions from measurement uncertainty on $L$, as well as “true” microphysical variability. The impact of changes in $L$ on retrieved $\mu$ is non-linearly related to $\mu$; $\sigma_L$ contributes more to retrieved $\mu$ variability for more monodisperse (higher $\mu$) DSDs, compared to more polydisperse (lower $\mu$) DSDs. Conversely, the contribution of $\sigma_L$ to retrieved $\mu$ variability decreases as $Z_{DR}$ increases, as the dual polarisation signature is larger and $\mu$ is more easily distinguishable (see Figure 8).

To estimate the contribution that the uncertainty on $L$ measurements makes to this observed variability, $\mu$ was retrieved using the median $L \pm$ the representative uncertainty depicted in Figure 9. This was then compared to the inter-quartile range of the retrieved $\mu$ for each $Z_{DR}$ bin. For $Z_{DR}$ bins of 0.8, 1, 1.2, 1.4 and 1.6 dB, we estimate that 88%, 66% 32%, 31% and 27% of the variability respectively can be attributed to $\sigma_L$. For $Z_{DR} > 1$ dB, most of the variability seen in Figure 10 can be attributed to “true” microphysical variability.

Figure 11 shows a comparison with retrieved $\mu$ for all of the case studies collected. Each of the dwells in January, April and November were made in stratiform rain, whereas the May case study contains dwells from convective rain. Overlayed are predicted mean $\mu$ values (solid grey) and upper and lower bounds that contain 55% of the measurements (dashed grey) of Williams et al. (2014) as a function of $Z_{DR}$ from the disdrometer measurements. The solid black line shows the predicted $\mu - Z_{DR}$ using the $\mu - \Lambda$ relationship of Cao et al. (2008). There is a large spread in the radar retrieved median $\mu$ values from case to case. Each median $\mu$ estimate is from a very large number of retrieved $\mu$ estimates, such that the standard error is smaller than the markers themselves, and so is not shown. The values of
retrieved $\mu$ in January are $\approx 0$, close to an exponential DSD for all $Z_{DR}$ smaller than 1.1 dB. This is below that predicted by Williams et al. (2014), but agrees well with $\mu$ predicted by Cao et al. (2008). Interestingly, the case studies of April and November show $\mu$ increasing with $Z_{DR}$ between 0.5 dB and 1.5 dB, compared to the trend seen by Williams et al. (2014) and Cao et al. (2008) towards an exponential DSD. The retrieved median $\mu$ values from the May case study, although agreeing with the decreasing trend with $Z_{DR}$, are significantly above the Cao et al. (2008) predictions and the upper bound of $\mu$ from Williams et al. (2014). Our retrieval suggests that in this case, the rain rate would be overestimated by almost 2 dB if an exponential DSD or the fit of Cao et al. (2008) is assumed. Whereas the $\mu$ values are not outside the full range of data measured by Williams et al. (2014), the use of the proposed $\mu - D_m$ relationship would cause an overestimate of $\approx 1$ dB (see Figure 1).

8. Discussion

Our retrievals of $\mu$ made using $\rho_{hv}$ and $Z_{DR}$ are typically larger than the radar estimates of $\mu$ of between 1—3 by Thurai et al. (2008) and 0—2 of Illingworth and Caylor (1991). Perhaps this is not surprising, given that the imperfect co-location of the $H$ and $V$ sample volumes was unaccounted for, and their $\hat{\rho}_{hv}$ would have been biased low due to averaging $\rho_{hv}$ rather than $L$, both of which are accounted for in our data. Furthermore, Illingworth and Caylor (1991) do not include drop oscillations in their retrievals, which will have led to a significant underestimate of $\mu$. Whereas there is some agreement of the magnitudes of $\mu$ for $Z_{DR} < 1$ dB with predicted Williams et al. (2014) and Cao et al. (2008) values, the apparent opposite trend towards more monodisperse distributions is consistent among 3 of the 4 case studies. For the retrieved $\mu$ to agree with the trend predicted by Williams et al. (2014) or Cao et al. (2008), a reduction in the drop oscillation amplitudes for smaller drops would be required so that predicted $L$ values are higher. However, this would not explain the difference between the May retrieval results and the predicted $\mu$ from disdrometer measurements; we
estimate that it would require oscillations that are at least an order of magnitude larger to bring these median $\mu$ estimates into agreement with Williams et al. (2014) or Cao et al. (2008). An incorrect parameterisation of the drop oscillations alone is unlikely to be able to account for the disagreement with Williams et al. (2014) and Cao et al. (2008), however, to better establish the accuracy of the technique, a better quantification of raindrop oscillations is desirable.

$\mu$ estimates derived using radar are sensitive to higher moments of the DSD, whereas disdrometer estimates tend to use lower moments of the DSD (Cao and Zhang 2009). This could be partly responsible for the differences between the radar and disdrometer estimated $\mu$ values. If the DSD shape is not perfectly described by Equation 1, the “effective” $\mu$ which is derived may be different even if the underlying DSD shape is the same. It is also possible that what we have captured is simply natural variability of the DSD in different types of rainfall (i.e convective and stratiform), and there is not a universal $\mu - D_0$ relationship. More case studies are needed to gather a statistical understanding of the behaviour of $\mu$ using this retrieval method.

a. Implications for Operational Use of $L$

Operational radar networks favour the use of rapid scan rates to maximise sample frequency and total sample volume. For UK Met Office radars observing rain with 1 ms$^{-1}$ Doppler spectral width, each gate contains $N_{IQ} \approx 11$ ($\sigma_L \approx 0.3$). Clearly, many more $N_{IQ}$ are needed than are available for individual gate estimates of $\mu$. Greater measurement precision can be achieved by averaging (with the confidence interval computed using the aggregated number of independent $I$ and $Q$ samples), and assuming $\mu$ is spatially conserved over the chosen averaging area. To obtain a $\mu$ estimate over approximately 1 km$^2$, for example, would require the averaging of 2 rays and 10 gates (at a range from the radar of 30 km); this $L$ estimate would be calculated using $N_{IQ} = 220$ ($\sigma_L \approx 0.058$). Whereas this may not be sufficient to distinguish $\mu$ to as high a resolution as our retrieval (which uses long
dwell as \( N_{IQ} > 1000 \), this will at least be able to decipher whether \( \mu \) is ‘high’ or ‘low’.

Practically, as illustrated in Figure 1, this may be all that is necessary to offer improved rain rate estimates; it is relatively unimportant whether \( \mu \) is 8 or 16, but it is very important to know if it is 0 or 4. Therefore, this method could (with sufficient care to ensure only rain echoes and good SNR) allow for improved rain rates using \( Z \), \( Z_{DR} \) and \( L \) compared to only \( Z \) and \( Z_{DR} \).

For the typical \( \sigma_L \) used in these calculations, we can approximate the error on the retrieved rain rate by considering the contribution of \( \sigma_L \) to the uncertainty in \( \mu \). For a ‘typical’ \( \mu \) of 6, the range of retrieved \( \mu \) is \( \approx \pm 4 \). By referring to Figure 1, we can see that this corresponds to a difference in rain rate of \( \pm 0.5 \) dB, or \( \pm 12.5\% \). The impact of uncertainty in \( \mu \) on rain rate is almost constant for all \( Z_{DR} \) (each of the \( \mu \) lines are approximately parallel in Figure 1 for \( Z_{DR} \gtrsim 0.5 \) dB). Therefore, this error will decrease for higher rain rates as the contribution of \( \sigma_L \) to uncertainty in \( \mu \) decreases as a function of \( Z_{DR} \).

9. Conclusions

In this paper, a new variable \( L = -\log_{10}(1 - \rho_{hv}) \) is defined that is Gaussian distributed with a width predictable by the number of independent \( I \) and \( Q \) samples, which in turn can be estimated using the Doppler spectral width. This allows, for the first time, the construction of rigorous confidence intervals on each \( \rho_{hv} \) measurement. The predicted errors using this new method were verified using high quality measurements in drizzle from the Chilbolton Advanced Meteorological Radar.

Importantly, the proposed method is of much greater practical use than the linear perturbation error estimation method, as it does not require knowledge of the unknown “true” \( \rho_{hv} \) that one is trying to estimate. The method works for both simultaneous or accurately interpolated alternate sampling. However, it does not work for alternate estimators which rely on the Gaussian autocorrelation function to estimate the zero-lag correlation between
and $V$ pulses (Sachidananda and Zrnic 1989), where $\rho_{hv}$ estimates can be $> 1$.

A new technique to account for the imperfect co-location of $H$ and $V$ sampling volumes on $\rho_{hv}$ measurements is presented. The impact of drop oscillations on the observed $L$ measurements was shown to be significant; omitting oscillations from our Gans simulations leads to an underestimate of retrieved $\mu$ of $\approx 8$. We further show that failure to use $L$ over $\rho_{hv}$ measurements when averaging can lead to a significant bias low in $\rho_{hv}$ estimates (and consequently $\mu$), particularly for very short dwell times such as those used operationally.

High-precision measurements of $L$ and $Z_{DR}$ in rainfall are then used to estimate $\mu$ in the gamma DSD for four case studies. We find that our estimates of $\mu$ in stratiform rain somewhat agree in magnitude with those from disdrometer studies for small $Z_{DR}$, but there appears to be a tendency to more monodisperse DSDs between $Z_{DR} = 0.8$ and 1.5 dB, unlike the trend towards an exponential distribution suggested by disdrometer measurements. The convective case study does display this trend toward lower $\mu$ as $Z_{DR}$ increases, but the magnitude of $\mu$ remains much larger than predicted by disdrometer measurements. If true, this would lead to overestimates of retrieved rain rate by $\approx 1$ dB if the $\mu - D_m$ relationship of Williams et al. (2014) is used, or 2 dB if an exponential distribution or the $\mu - \Lambda$ relationship of Cao et al. (2008) is used. We find that the $\mu$ retrieval exhibits sensitivity to the choice of drop oscillation model. A better understanding of raindrop oscillations would be useful to fully establish the accuracy of our retrieval technique.

The variability in our radar retrieved $\mu$ could simply be natural variability of the DSD between convective and stratiform rainfall; there may not be a universal $\mu - D_0$ relationship. More case studies are desirable to investigate this further.

The $\mu$ retrieval technique employed here offers improvements over the radar estimates of Illingworth and Caylor (1991) and Thurai et al. (2008). Illingworth and Caylor (1991) did not take into account the imperfect co-location of the $H$ and $V$ sample volumes on measurements of $\rho_{hv}$, the effect of drop oscillations, or the fact their $\rho_{hv}$ estimates would be biased low by averaging short time-series. Each of these effects would cause $\mu$ to be
underestimated. The same is true of Thurai et al. (2008), however drop shapes measured by
2DVD measurements include oscillations, and so are included in their $\mu$ estimates.

The new error statistics of $\rho_{hv}$ presented here could aid operational applications that
require uncertainty on $\hat{\rho}_{hv}$ to be quantified, or use averages of $\rho_{hv}$. The use of $L$ operationally
to retrieve $\mu$ is limited by use of rapid scan rates and the corresponding few independent
$I$ and $Q$ samples. However, assuming that $\mu$ is a smoothly varying parameter, averaging
$L$ could help improve rain rate retrievals; the uncertainty on operationally retrieved rain
rates using the retrieval technique presented here is estimated to be approximately $\pm 12.5\%$.
Practically, retrieved rain rates are less affected by changes in higher values of $\mu$ compared
to changes in lower values. Therefore, operationally, simply being able to distinguish regions
of ‘high’ and ‘low’ $\mu$ with $L$ could be sufficient to provide an improvement over existing
$Z - Z_{DR}$ retrieval techniques.

APPENDIX

The effect of imperfectly co-located H and V samples on $\rho_{hv}$

Consider two measurements of the (complex) amplitudes at horizontal and vertical polar-
isation $A_H$ and $A_V$. If the two polarisations do not have perfectly matched sample volumes,
then each amplitude is the sum of (i) a component which is common to both polarisations
$C_H, C_V$, (ii) a component which is different for each polarisation $D_H, D_V$:

$$A_H = C_H + D_H$$

(and similarly $A_V = C_V + D_V$). The co-polar correlation coefficient is:

$$\rho_{hv} = \frac{\sum A_H A_V^*}{\sqrt{\sum |A_H|^2 \sum |A_V|^2}}$$

where the sums $\sum$ are taken over many reshufflings of the raindrops. Substituting in the
expressions for $A_H$ and $A_V$ leads to:
\[ \rho_{hv} = \frac{\sum C_H C_V^* + \sum D_H C_V^* + \sum C_H D_V^* + \sum D_H D_V^*}{\sqrt{\sum |C_H + D_H|^2 \sum |C_V + D_V|^2}} \]  

(A3)

The first term in the numerator dominates as the number of pulses is increased. This is because \( D_H, D_V, \) are uncorrelated with \( C_V, C_H \) (because the reshuffling of particles in the different sample volumes is not connected or organised in any way), while \( C_H \) and \( C_V \) are highly correlated (because the true \( \rho_{hv} \) is close to 1). The final term is small because \( D_H, D_V, \) are not correlated (by the same argument), and this term is small in any case since \(|D| \ll |C|\)

This leaves us with:

\[ \rho_{hv} = \frac{\sum C_H C_V^*}{\sqrt{\sum |C_H + D_H|^2 \sum |C_V + D_V|^2}} \]  

(A4)

In the case of a perfect radar with perfect co-location of the \( H \) and \( V \) samples, then \( D_H, D_V \) are zero and we get a correlation coefficient which is the true \( \rho_{hv} \) which we are trying to obtain (ie setting \( A = C \) in equation A2).

In general, for an imperfect radar, we have \( D_H, D_V > 0 \) and from the results above we see that:

\[ \rho_{hv} = \rho_{hv}^{\text{true}} \times f_{hv}^{\text{max}} \]  

(A5)

where

\[ f_{hv}^{\text{max}} = \left( \frac{\sum |C_H|^2}{\sum |C_H + D_H|^2} \times \frac{\sum |C_V|^2}{\sum |C_V + D_V|^2} \right)^{1/2} \]  

(A6)

This result is directly analogous to the results of Bringi et al. (1983) on \( \rho_{hv} \) in the presence of noise. If we identify \( C \) as our “signal” and \( D \) as our “noise” this equation is identical to Equation A1.

Crucially, the relationship between the true \( \rho_{hv} \) (\( \rho_{hv}^{\text{true}} \)) and the one which is actually observed is determined simply by how much power (on average over many pulses) comes
from the particles which are different for the H and V sample volumes, relative to how much
power comes from the particles which are common to the H and V sample volumes, and that
this factor should be constant for different microphysical situations. Thus if we can measure
\( \rho_{hv} \) in drizzle where we know \( \rho_{hv}^{\text{true}} = 1 \), then the measured \( \rho_{hv} \) is simply equal to \( f_{hv}^{\text{max}} \). This
scaling factor can then be applied to data from all other situations.

List of Figures

1 Rain rate (in dB referenced to 1 mm hr\(^{-1}\)) per unit radar reflectivity as a function of \(Z_{DR}\) computed using Gans theory for gamma distributions of \(\mu = -1, 0, 2, 4, 8, 12\) and 16. The rain rate can vary by as much as 2.5 dB for a given pair of \(Z\) and \(Z_{DR}\) observations as a result of drop spectrum shape variability.

2 Example time-series (0.5 s) for single 75 m gates from 1.5\(^{\circ}\) elevation dwells in (a) drizzle (\(Z_{DR} = 0\) dB) at 1203 UTC on 6 February 2014, and (b) heavier rainfall (\(Z_{DR} = 1.1\) dB) at 1706 UTC on 31 January 2014. For both examples, SNR > 40 dB. For drizzle, the \(H\) and \(V\) echo time-series vary in unison as the drops are all spherical. In heavier rainfall, the broader axis ratio distribution causes the \(H\) and \(V\) time-series to be less correlated. The rate of fluctuation of the signals is determined by the Doppler spectral width.

3 The frequency distribution of (a) \(\hat{\rho}_{hv}\) calculated from 1159 time-series (0.21 s, 75 m gates) in drizzle (\(Z_{DR} < 0.1\) dB) and (b) \(\hat{L} = -\log_{10}(1-\hat{\rho}_{hv})\). The data was collected at 1203 UTC on 6 February 2014 during a 1.5\(^{\circ}\) elevation dwell and has very high SNR (> 40 dB). \(\sigma_v\) for these data ranges between 0.9—1.3 ms\(^{-1}\). Overplotted on \(\hat{L}\) is a Gaussian curve with same mean and standard deviation as the measured distribution.

4 \(\sigma_L\) as a function of the number of independent \(I\) and \(Q\) samples used to estimate \(L\) for high SNR measurements in drizzle (\(Z_{DR} < 0.1\) dB, SNR > 40 dB) at 1203 UTC on 6 February. Different markers correspond to different Doppler spectral widths.
(a) A comparison of the confidence intervals calculated using the new method and that of Torlaschi and Gingras (2003) in rain ($\rho_{hv} = 0.98$) and (b) the bias introduced by averaging $\rho_{hv}$ instead of $\hat{L}$, as a function of $N_{IQ}$. For all $N_{IQ}$, the lower confidence interval is higher for the Torlaschi and Gingras (2003) method, particularly for lower $N_{IQ}$, due to the asymmetric nature of the confidence intervals on $\rho_{hv}$ using the new method. Averaging $\rho_{hv}$ and not $\hat{L}$ for small $N_{IQ}$ can lead to a large bias.

(a) Comparison of mean drop axis ratios as a function of equivalent drop diameter ($D$) from recent experiments of Thurai and Bringi (2005), Szakáll et al. (2008) and the 4th order polynomial fit of older experimental data constructed by Brandes et al. (2002). The model of Thurai and Bringi (2005) has been adapted so that drops are spherical for $D < 1$ mm. Panels (b)—(d) show radar and disdrometer $Z_{DR}$ comparisons calculated using Thurai and Bringi (2005), Szakáll et al. (2008) and Brandes et al. (2002) from a 5 hour dwell over a nearby Joss-Waldvogel RD-80 impact disdrometer (approximately 7 km away) in a frontal rain band on 25 April 2014. The time resolution of the radar measurements was decreased to 30 s to match the integration time of the disdrometer. At a 1.5° elevation angle, the radar was sampling rain at a height of $\approx 183$ m above the disdrometer. The dashed line is a 1:1 line. The smallest biases are achieved with the Thurai and Bringi (2005) model, especially for smaller $Z_{DR}$, suggesting that these shapes best represent those of natural rain drops. Therefore, this model is chosen for the analysis.

Predicted $L$ and $Z_{DR}$ values for gamma distributions of $\mu = -1$ (solid) and 16 (dashed) with no oscillations (grey), and including oscillations (black). The inclusion of drop oscillations are crucial to interpretation of $L$ and $Z_{DR}$ measurements. The $f_{hv}^{max}$ is assumed to be 0.9963 to match the case study in Section 7.
Theoretical $L$ and $Z_{DR}$ computed using Gans theory for gamma distributions with $\mu = -1, 0, 2, 4, 8, 12$ and 16, using Thurai and Bringi (2005) mean drop axis ratios and oscillation model described in Section 6b. The precision of $L$ required to estimate $\mu$ decreases as $Z_{DR}$ increases. The $f_{hv}^{max}$ is assumed to be 0.9963 to match the case study in Section 7.

(a) 2D PDF of $L$ and $Z_{DR}$ observations, and (b) normalised 2D PDF such that the distribution equals 1 for each $Z_{DR}$ bin for observations of $L$ and $Z_{DR}$ collected from dwells on 25 November 2014. $L$ is binned every 0.02, and $Z_{DR}$ every 0.05 dB. Overplotted are theoretical $L$ and $Z_{DR}$ computed using Gans theory for gamma distributions of $\mu = -1, 0, 2, 4, 8, 12$ and 16. Typical errors on $L$ and $Z_{DR}$ are shown as error bars; the error on $Z_{DR}$ is very small. The grey dashed line is the predicted $L$ and $Z_{DR}$ observations using DSD parameters from the power-law fit to disdrometer measurements in Williams et al. (2014). The black dashed line is the predicted $L$ and $Z_{DR}$ observations using the $\mu - \Lambda$ relationship of Cao et al. (2008). The $f_{hv}^{max}$ for this day is measured to be 0.9963.

Box plot of retrieved $\mu$ as a function of $Z_{DR}$ for $Z_{DR}$ bins of 0.2 dB on 25 November 2014, showing the median and inter-quartile range of the data.

Median retrieved $\mu$ as a function of $Z_{DR}$ for $Z_{DR}$ bins of 0.1 dB for case studies of 31 January, 25 April, 22 May and 25 November 2014. The solid line is the predicted $\mu$ as a function of $Z_{DR}$ from the power law fit to disdrometer measurements of Williams et al. (2014), and $\sigma_\mu$ corresponds to the upper and lower bounds that contain 55% of the data. The solid black line shows the predicted $\mu - Z_{DR}$ using the $\mu - \Lambda$ relationship of Cao et al. (2008).
Fig. 1. Rain rate (in dB referenced to 1 mm hr\(^{-1}\)) per unit radar reflectivity as a function of \(Z_{DR}\) computed using Gans theory for gamma distributions of \(\mu = -1,\ 0,\ 2,\ 4,\ 8,\ 12\) and 16. The rain rate can vary by as much as 2.5 dB for a given pair of \(Z\) and \(Z_{DR}\) observations as a result of drop spectrum shape variability.
Fig. 2. Example time-series (0.5 s) for single 75 m gates from 1.5° elevation dwells in (a) drizzle ($Z_{DR} = 0$ dB) at 1203 UTC on 6 February 2014, and (b) heavier rainfall ($Z_{DR} = 1.1$ dB) at 1706 UTC on 31 January 2014. For both examples, SNR > 40 dB. For drizzle, the $H$ and $V$ echo time-series vary in unison as the drops are all spherical. In heavier rainfall, the broader axis ratio distribution causes the $H$ and $V$ time-series to be less correlated. The rate of fluctuation of the signals is determined by the Doppler spectral width.
Fig. 3. The frequency distribution of (a) $\hat{\rho}_{hv}$ calculated from 1159 time-series (0.21 s, 75 m gates) in drizzle ($Z_{DR} < 0.1$ dB) and (b) $\hat{L} = -\log_{10}(1-\hat{\rho}_{hv})$. The data was collected at 1203 UTC on 6 February 2014 during a $1.5^\circ$ elevation dwell and has very high SNR (> 40 dB). $\sigma_v$ for these data ranges between 0.9—1.3 ms$^{-1}$. Overplotted on $\hat{L}$ is a Gaussian curve with same mean and standard deviation as the measured distribution.
Fig. 4. $\sigma_L$ as a function of the number of independent $I$ and $Q$ samples used to estimate $L$ for high SNR measurements in drizzle ($Z_{DR} < 0.1$ dB, SNR > 40 dB) at 1203 UTC on 6 February. Different markers correspond to different Doppler spectral widths.
Fig. 5. (a) A comparison of the confidence intervals calculated using the new method and that of Torlaschi and Gingras (2003) in rain ($\bar{\rho}_{hv} = 0.98$) and (b) the bias introduced by averaging $\hat{\rho}_{hv}$ instead of $\hat{L}$, as a function of $N_{IQ}$. For all $N_{IQ}$, the lower confidence interval is higher for the Torlaschi and Gingras (2003) method, particularly for lower $N_{IQ}$, due to the asymmetric nature of the confidence intervals on $\rho_{hv}$ using the new method. Averaging $\hat{\rho}_{hv}$ and not $\hat{L}$ for small $N_{IQ}$ can lead to a large bias.
Fig. 6. (a) Comparison of mean drop axis ratios as a function of equivalent drop diameter \((D)\) from recent experiments of Thurai and Bringi (2005), Szakáll et al. (2008) and the 4\textsuperscript{th} order polynomial fit of older experimental data constructed by Brandes et al. (2002). The model of Thurai and Bringi (2005) has been adapted so that drops are spherical for \(D < 1\) mm. Panels (b)—(d) show radar and disdrometer \(Z_{DR}\) comparisons calculated using Thurai and Bringi (2005), Szakáll et al. (2008) and Brandes et al. (2002) from a 5 hour dwell over a nearby Joss-Waldvogel RD-80 impact disdrometer (approximately 7 km away) in a frontal rain band on 25 April 2014. The time resolution of the radar measurements was decreased to 30 s to match the integration time of the disdrometer. At a 1.5\degree elevation angle, the radar was sampling rain at a height of \(\approx 183\) m above the disdrometer. The dashed line is a 1:1 line. The smallest biases are achieved with the Thurai and Bringi (2005) model, especially for smaller \(Z_{DR}\), suggesting that these shapes best represent those of natural rain drops. Therefore, this model is chosen for the analysis.
Fig. 7. Predicted $L$ and $Z_{DR}$ values for gamma distributions of $\mu = -1$ (solid) and 16 (dashed) with no oscillations (grey), and including oscillations (black). The inclusion of drop oscillations are crucial to interpretation of $L$ and $Z_{DR}$ measurements. The $f_{hv}^{\text{max}}$ is assumed to be 0.9963 to match the case study in Section 7.
Fig. 8. Theoretical $L$ and $Z_{DR}$ computed using Gans theory for gamma distributions with $\mu = -1, 0, 2, 4, 8, 12$ and 16, using Thurai and Bringi (2005) mean drop axis ratios and oscillation model described in Section 6b. The precision of $L$ required to estimate $\mu$ decreases as $Z_{DR}$ increases. The $f_{hv}^{max}$ is assumed to be 0.9963 to match the case study in Section 7.
Fig. 9. (a) 2D PDF of $L$ and $Z_{DR}$ observations, and (b) normalised 2D PDF such that the distribution equals 1 for each $Z_{DR}$ bin for observations of $L$ and $Z_{DR}$ collected from dwells on 25 November 2014. $L$ is binned every 0.02, and $Z_{DR}$ every 0.05 dB. Overplotted are theoretical $L$ and $Z_{DR}$ computed using Gans theory for gamma distributions of $\mu = -1, 0, 2, 4, 8, 12$ and 16. Typical errors on $L$ and $Z_{DR}$ are shown as error bars; the error on $Z_{DR}$ is very small. The grey dashed line is the predicted $L$ and $Z_{DR}$ observations using DSD parameters from the power-law fit to disdrometer measurements in Williams et al. (2014). The black dashed line is the predicted $L$ and $Z_{DR}$ observations using the $\mu - \Lambda$ relationship of Cao et al. (2008). The $f_{hv}^{max}$ for this day is measured to be 0.9963.
Fig. 10. Box plot of retrieved $\mu$ as a function of $Z_{DR}$ for $Z_{DR}$ bins of 0.2 dB on 25 November 2014, showing the median and inter-quartile range of the data.
Fig. 11. Median retrieved $\mu$ as a function of $Z_{DR}$ for $Z_{DR}$ bins of 0.1 dB for case studies of 31 January, 25 April, 22 May and 25 November 2014. The solid line is the predicted $\mu$ as a function of $Z_{DR}$ from the power law fit to disdrometer measurements of Williams et al. (2014), and $\sigma_{\mu}$ corresponds to the upper and lower bounds that contain 55% of the data. The solid black line shows the predicted $\mu - Z_{DR}$ using the $\mu - \Lambda$ relationship of Cao et al. (2008).
