Keywords: urban hydrology, precipitation, land surface model, SUEWS, WFDEI, downscaling

Abstract

Often the meteorological forcing data required for urban hydrological models are unavailable at the required temporal resolution or for the desired period. Although reanalysis data can provide this information, the spatial resolution is often coarse relative to cities, so downscaling is required prior to use as realistic forcing. In this study, WATCH WFDEI reanalysis data are used to force the Surface Urban Energy and Water balance Scheme (SUEWS). From sensitivity tests in two cities, Vancouver and London with different orography, we conclude precipitation is the most important meteorological variable to be properly downscaled to obtain reliable surface hydrology results, with relative humidity being the second most important. Overestimation of precipitation in reanalysis data at the three sites gives 6–21 % higher annual modelled evaporation, 26–39 % higher runoff at one site and 4 % lower value at one site when compared to modelled values using observed forcing data. Application of a bias correction method to the reanalysis precipitation reduces the model bias compared to using observed forcing data, when evaluated using eddy covariance evaporation measurements.

1. Introduction

Modelling urban water balance components, including evaporation and runoff, are crucial to understand, forecast and predict the hydrological cycle (including extreme events) in cities. With current global urban growth and development, there is increasing need for fine-scale hydrological information, particularly in areas where few or no routine observations exist, or under future urbanization scenarios.

The high fraction of impervious surfaces in urban areas generally increases surface runoff flow velocities and volumes and decreases infiltration and evaporation, all altering the probability of flooding (e.g. Rodriguez et al., 2003). High volumes of urban runoff impact water quality and hydrological regimes in local streams, inland waters and coastal zones, modifying ecological conditions and increasing the environmental burden (Knight and Cuffney, 2012; Konrad and Booth, 2002; Paul and Meyer, 2001). Detailed information is needed (e.g. from numerical models and/or from observational campaigns) in different macroclimates and city structures (e.g. city centre and suburban areas) to inform urban development. To undertake fine-scale urban hydrological modelling (Kanamitsu and Kanamaru, 2007; Wood, 2004) detailed, location-specific meteorological forcing data are required. High-resolution input data allow rapid changes in hydrological conditions (e.g. after a heavy rain event) to be explored. However direct observations of required variables to force urban climate and hydrological models are rare. Grimmond et al. (2010b) and the 5th assessment report of the Intergovernmental Panel on Climate Change (IPCC, 2014) have highlighted the lack of urban observations and the need to have observations in a greater variety of locations. Due to the complexity and diversity of cities observational studies are typically limited to individual sites in a few cities.

Global reanalysis products can provide the essential variables to enable modelling where and when observations are unavailable (e.g. in data sparse regions of the world where cities are growing rapidly, or for past events before instruments were installed). Reanalysis data can also be used to supplement datasets that are missing required variables, or to provide higher temporal resolution data if only coarse information is available (e.g. daily totals). Reanalysis data are generated by rerunning global meteorological models but with data assimilation of a large amount of observations (e.g. remote sensing and ground based observations). Although there are a number of reanalysis products available (e.g. ERA-Interim (Dee et al., 2011), MERRA (Rienecker et al., 2011), JRA-55 (Kobayashi et al., 2015), NCEP (Kalnay et al., 1996), WFDEI (Weedon et al., 2014)), they are typically spatially coarse (e.g. 0.5°). This means that downscaling is needed prior to use for local-scale urban hydrological modelling (Bastola and Misra, 2014; Fowler et al., 2007; Wilby et al., 2000). For example, large variations in topography can cause the mean grid height of the reanalysis product to be different from the height of the study site (Frei et al., 2003). As the fine-scale distribution of precipitation is highly dependent on orography (e.g. Brunsdon et al., 2001; Oke and Hay, 1994), accounting for it may be crucial for reliable model results (e.g. Bastola and Misra, 2014). Convection-resolving numerical weather prediction allows precipitation distributions to be modelled (Brisson et al., 2016) but requires a large amount of computer resources for climate runs. Although this method has the advantage of not requiring *a priori* observations for application, convection-resolving modelling is an area of active research because of the many challenges with cloud processes relative to the grid size (Holloway et al., 2014).

To reduce the computational needs for applications, bias correction with quantile mapping (BCQM) has been found to be an effective method to correct daily precipitation intensities in climate projections (e.g. Gudmundsson et al., 2012; Rätty et al., 2014; Sunyer et al., 2015; Teutschbein and Seibert, 2012). Although this method has the disadvantage of requiring observations to undertake the corrections, it does retain the observed distributions as a constraint. As the temporal resolution of reanalysis products is typically 3 to 6 h, i.e. too coarse for detailed hydrological modelling (Bastola and Misra, 2014), interpolation to finer temporal resolution is needed. To date, reanalysis products have been little used in the modelling of urban water and energy

exchanges. As the WATCH WFDEI reanalysis data (Weedon et al. 2011, 2014) are specifically derived for hydrological modelling from ERA-Interim, and have been used to model surface energy fluxes in 20 different urban areas (Best and Grimmond 2016), they are chosen for this study.

There are a large number of urban land surface models (Grimmond et al., 2009) that take a wide variety of approaches to describing urban surface exchange processes (Grimmond et al. 2010a, 2011). Given the importance of vegetation to urban hydrology and turbulent exchange (Best and Grimmond, 2014, 2016) and its significant presence in suburban areas and central business districts it is critical that a scheme can simulate its influence on the surface energy and water balances (Best and Grimmond, 2013, 2014; Grimmond et al., 2011; Loridan and Grimmond, 2012; Nordbo et al., 2015). Where many gardens and parks are present, irrigation can become an important component of the local water balance (Grimmond and Oke, 1986; Mitchell et al., 2001, 2003) thereby also influencing energy exchange.

The urban land surface model used in this study is the Surface Urban Energy and Water balance Scheme (SUEWS). This local (neighbourhood) scale scheme can simulate both energy and water balance components (Järvi et al., 2011, 2014; Ward et al., 2016b) including vegetation and irrigation but, is simple enough to handle multiple grids and several years without special computational power. It requires only basic meteorological data and surface information as inputs. With the procedures described in this paper, SUEWS can be run with limited local observations by using reanalysis data as forcing.

The objective of this study is to assess the impact of reanalysis forcing data on the performance of an urban land surface and water balance model in two cities: Vancouver, Canada, and London, UK (Section 2.1). To force the model (SUEWS, Section 2.2) the WATCH WFDEI (Weedon et al., 2014) reanalysis data (Section 2.3) are used. The precipitation reanalysis data are corrected to improve the spatial representativeness of the data for the study area relative to the WFDEI grid box (Section 2.3.1). First the sensitivity of the model to the required meteorological data is examined (Section 3.1), second the effect of bias correction to precipitation is examined (Section 3.2) and third the performance of SUEWS running with reanalysis data is examined (Section 3.3). The model output using both observed and reanalysis data (both corrected and uncorrected) as forcing are compared against evaporation measured with the eddy covariance technique at one site in both Vancouver and London. The consideration of multiple sites in different cities allows different urban land covers and weather patterns to be considered. Although, errors in model performance can arise from model parameterizations, this is the focus of other papers (e.g. Alexander et al. 2016, Karsisto et al. 2015, Ward et al. 2016b) and not specifically addressed here.

2. Methods

2.1 Study areas and sites

Vancouver and London both experience maritime temperate climates (Met Office, 2016; Oke and Hay, 1994). The more topographically diverse Vancouver (Figure 1) has an enhancement of 100 mm annual precipitation per 100 m increase in elevation (Oke and Hay, 1994). Near sea level, precipitation is approximately 900 mm y⁻¹ (South Richmond) whereas the nearby mountains record over 3500 mm y⁻¹ (Hollyburn 1326 m, Grouse 1231 m). Winter precipitation is approximately four times greater than in summer (Figure 2; Oke and Hay, 1994).

The study sites in Vancouver are two suburban neighbourhoods, “Vancouver-Oakridge” and “Vancouver-Sunset” (Table 1), that are approximately 3 km apart on a fairly flat terrain (Figure 1). The annual precipitation at both areas is approximately 1000 mm y⁻¹ (Environment Canada, 2015). The two residential areas have 1-2 storey single-family dwellings (LCZ 6, Stewart and Oke, 2012), but differ in their characteristic lot and building size and land cover (Table 1). The impervious surface cover fraction is larger in the more densely populated area Vancouver-Sunset (68 %, almost three times as many inhabitants) than in Vancouver-Oakridge (44 %) (Table 1). In addition, the amount and area of irrigation varies between the sites further affecting the local water balance.

London is occasionally influenced by continental weather that brings cold spells in winter and hot and humid weather in summer (Met Office, 2016). The mean annual rainfall in central London is 570 mm y⁻¹ (St. James's Park meteorological station for 1980–1999, see Section 2.3.1; Met Office, 2015). This rainfall, generally, is evenly distributed through the year (Figure 2), with significant amounts of showery convective rainfall in the summer. The focus of this study is the central business district of Westminster (Figure 1). There are extensive impervious surfaces (81 %) with little vegetation (5 %, Table 1) but with insignificant irrigation. The area has a large daytime population and a high volume of traffic (Greater London Authority, 2015) making anthropogenic heat fluxes important (Ward et al., 2016b, 2017).

Forcing and evaluation data are available from observations in both cities. Modelled evaporation is compared with the eddy covariance (EC) observations at Vancouver-Sunset (Christen et al., 2011) and London (Kotthaus and Grimmond, 2014a, b). At both sites, sonic anemometers (CSAT3 Campbell Scientific) with open path infrared gas analysers (Li-7500 Licor Inc.) are used. Other measured variables needed for model forcing include incoming shortwave radiation K_{\downarrow} , precipitation P , air temperature T_a , station pressure p , relative humidity RH , and wind speed U . At Vancouver-Oakridge, no EC observations were available. The meteorological observations used as model forcing are described in Grimmond and Oke (1986).

Long-term observations of daily precipitation needed for a calibration period of the reanalysis data correction (Section 2.4.1) were made with tipping bucket rain gauges at Vancouver-Oakridge (1990–2008) (Environment Canada, 2015) and St. James's Park (1980–1999) (Met Office, 2015). These long-term observations are available with a daily resolution, whereas the on-site

measurements are averaged to 1 h resolution. The relative locations of the long-term measurements, the site-specific measurements and the reanalysis grid are shown in Figure 1 for both Vancouver and London.

2.2 SUEWS model overview

In this study, version V2016a of the Surface Urban Energy and Water balance Scheme (SUEWS) is used (Ward et al., 2016a). The model is run with a 5-min time step to capture rapid changes in the water balance, for example in a convective rain event. SUEWS primary spatial scale corresponds to that used in planning and design related to land use, land cover and infrastructure in cities (Kellett et al., 2013). Physical processes (e.g. evaporation, interception) are modelled for seven surface types (paved, buildings, evergreen trees/shrubs, deciduous trees/shrubs, grass, bare soil and water). In SUEWS, the water state of each surface is calculated from a running water balance accounting for evaporation, runoff and drainage (Grimmond and Oke, 1991). Below each surface type, except water, there is a single soil layer. The fluxes calculated for an individual time step are a function of the proportion of the component surface types in the area. The net change in water storage is determined from the combined changes in surface states and soil moisture.

Model performance in terms of urban hydrology has been found to be largely dependent on the impervious water storage formulation and parameters (Wouters et al., 2015). The net all-wave radiation is simulated using the net all-wave radiation scheme (NARP; Loridan et al., 2011; Offerle et al., 2003) and storage heat flux using the Objective Hysteresis Model (OHM, Grimmond et al., 1991). Anthropogenic heat flux is calculated based on heating and cooling degree-days, assuming a base temperature of 18.2 °C above which cooling and below which heating of the buildings takes place (Järvi et al., 2011). Latent heat flux (evaporation) is calculated using the modified Penman-Monteith equation and sensible heat flux is taken as the residual from the other energy balance components. During each 5-min time step, the surface and soil water storages, water movements between the storages and surface runoff are calculated. The model needs meteorological data (section 2.1) and information about the cover fractions of the seven surface types, tree and building heights and population density (Table 1).

2.3 Reanalysis data and corrections

Similar to Best and Grimmond (2016), the WATCH Forcing Data ERA-Interim (WFDEI) (Weedon et al., 2014) are used to derive the model forcing data. The WFDEI dataset is derived for hydrological modelling purposes from the ERA-Interim reanalysis product (Dee et al., 2011) via sequential interpolation to half-degree spatial resolution with 3 h temporal resolution. WFDEI includes two precipitation datasets with different bias corrections: Climatic Research Unit's CRU TS3.101 (Harris et al., 2013) and Global Precipitation Climatology Centre's GPCCv5 (Schneider et al., 2013). In this study, GPCC data are used for the better station density. Only stations on land area are used for precipitation estimations.

The WFDEI data are interpolated from 3 h to 1 h (default for SUEWS) resolution. WFDEI average rainfall for the previous 3 h ($\text{kg m}^{-2} \text{s}^{-1}$) is converted to mm h^{-1} by assuming the rain rate is constant for the period. Given the focus on the long-term water balance this is taken as reasonable. In both Vancouver and London most precipitation is from frontal rain, although London experiences showery convective rain in summer months. London also has considerable contribution from stratiform clouds often lasting for a day or longer. Specific humidity (q), p and T_a are linearly interpolated from 3 h to 1 h. $K\downarrow$ is interpolated to 1 h using a method that takes into account its strong diurnal cycle which otherwise would cause issues around sunrise and sunset. Figure 3 shows WFDEI $K\downarrow$ compared to the observations at Vancouver and London sites. The observations in Vancouver-Oakridge are in apparent time while the WFDEI data are in local time, so there is a small time shift between the data and thus are not fully comparable at hourly resolution. As the correlation is very good ($r > 0.91$, $\text{RMSE} < 92 \text{ W m}^{-2}$), $K\downarrow$ is used without any additional corrections. In addition, the timestamp of the WFDEI data is changed from UTC to local time of the site.

The WFDEI grid height is the areally weighted mean height of the topography in each grid. In Vancouver, with mountains in the north (Figure 1), the grid height is 213 m above sea level (asl), whereas in London it is 78 m asl. The appropriate simulation height needs to consider the land elevation of the area of interest, the height of the roughness elements (buildings, trees) and the appropriate height for the forcing data for the simulation (e.g. height of evaluation observations if undertaking a comparison). The simulation heights used are 106 m asl for Vancouver-Sunset, 113 m asl for Vancouver-Oakridge, and 61 m asl for London.

The WFDEI T_a and p are adjusted to the simulation height using environmental lapse rate ($\Gamma = -6.5 \text{ °C km}^{-1}$) and the hypsometric equation (Weedon et al. 2010). RH , used by SUEWS, is calculated from the WFDEI specific humidity assuming it is constant with altitude to avoid supersaturation.

Interpolation requires a spin up period to avoid interpolation errors and missing data points at the beginning and at the end of the time series. Here, periods of one month before and after the main study periods are used.

2.3.1 Bias correction of the precipitation

Bias correction with quantile mapping (BCQM) following Rätty et al. (2014) and Räisänen and Rätty (2013, see their Figure 5) is used to adjust daily precipitation towards the observed precipitation. In addition to mean precipitation the method corrects the spread and shape of the daily precipitation distribution. In the process (Figure 4) the data are brought to 1 h temporal resolution using the relation between the uncorrected and BCQM-corrected WFDEI precipitation.

Quantile mapping techniques create a one-to-one mapping between two cumulative distribution functions of reanalysis data and observations (Sun et al., 2011). Cumulative distribution functions of the observed (F_o) and WFDEI (F_c) daily precipitation are first estimated for a calibration period (1990–2008 in Vancouver, 1980–1999 in London). Long calibration periods, typically in the order of 30 years (e.g. Dosio and Paruolo, 2011), are suggested in order to take decadal climate variability into account (e.g. Piani et al., 2010). BCQM transforms the whole reanalysis precipitation time series (s_i) into the bias corrected one (P_i) according to:

$$P_i = F_o^{-1}(F_c(s_i)). \quad (1)$$

Before the transformation, F_o^{-1} and F_c^{-1} are smoothed by taking a running mean over a range of quantiles to reduce noise, particularly in the upper tail of the distribution. For example, the smoothed quantiles for the reanalysis data in the calibration period (F_c^{-1}) are obtained as

$$\tilde{F}_c^{-1}(x) = \frac{\int_{\max(x-a,0)}^{\min(x+a,1)} F_c^{-1}(x) dx}{\int_{\max(x-a,0)}^{\min(x+a,1)} dx}, \quad (2)$$

where $x \in [0,1]$ and a is the smoothing parameter, giving the range of quantiles over which smoothing is applied. R  ty et al. (2014) recommend a small value for a , as the smoothing tends to contract the distribution, making the correction less accurate in the upper tail (i.e. extremely intense precipitation). After sensitivity tests (see Section 3.2), a is set to 0.04 for Vancouver and 0.00 (no smoothing) for London. This means that, for example, $\tilde{F}_c^{-1}(1)$ in Vancouver equals the mean of the highest 4 % of the precipitation in the calibration period.

If values of the full WFDEI time series are outside of the range of values in the calibration period, there is a need for extrapolation in the quantile-quantile relation. In this case, bias corrected values are obtained assuming constant relative change above the maximum of the calibration period distribution.

The reanalysis precipitation values are adjusted separately for each day of year using BCQM. To further reduce the effect of noise in the estimation of biases, a linear moving window (width W), centred around the day under consideration, is used to increase the amount of data used in assessing biases. After sensitivity tests (see Section 3.2), W is set to 51 for Vancouver and 61 for London. Note, parameter values a and W are not universal, so different values might be optimal in other cases.

SUEWS is designed to run with input data at 1 h resolution. However, due to observational constraints, precipitation is bias corrected at daily temporal resolution. Assuming that the within-day temporal variability is approximately captured by the WFDEI dataset and that hourly precipitation intensities have similar biases within a day. The corrected hourly values are obtained by simply adjusting the hourly precipitation intensities with a constant factor defined by the relation between daily uncorrected and BCQM-corrected WFDEI precipitation. Although these assumptions are rather strong, they should provide reasonable results at seasonal and annual scales, which are the main interest in this study.

2.4 Experimental outline

The SUEWS model (Section 2.2) runs are made using hourly, locally measured data (Section 2.1) (hereafter the control run) and WFDEI reanalysis data (Section 2.3) as a forcing. The latter includes both quantile mapping bias corrected (BCQM) (Section 2.3.1) and uncorrected WFDEI data. The sensitivity of the model to the reanalysis data is examined by changing each variable in the measured forcing data to the reanalysis data independently.

The SUEWS model performance is evaluated by comparing model outputs against observed evaporation. All runs at each site, whether using measured or reanalysis forcing data, have the same surface and population information. Surface cover fractions, building and tree heights, initial conditions and other parameter values are adapted from J  rvi et al. (2011) for the Vancouver sites and from Ward et al. (2016b) for London (Table 1).

For London and Vancouver-Sunset a full year is simulated (2012 and 2009, respectively) for the EC footprint area and Vancouver-Oakridge is simulated for 22 January 1982 - 21 January 1983 for the water monitoring area (Grimmond and Oke, 1986). This will be referred as the *study year*. Hereafter the sites are referred to as Lo12, Vs09 and Vo82, respectively.

3. Results and discussion

3.1 The sensitivity of SUEWS to its forcing data

To identify the meteorological variables SUEWS is most sensitive to, and therefore should be corrected, each input variable is independently examined. SUEWS is run with observed forcing data systematically replacing each variable with the WFDEI equivalent. To assess this, the simulated cumulative evaporation and runoff using the different combinations of forcing data are compared to the control run at each of the three studied sites.

In Vancouver, using most of the input WFDEI variables results in a higher total evaporation and runoff compared to the control run (Table 3). Only four variables in Vo82, and two variables in Vs09, give slightly smaller totals of evaporation (1–4 %) and two variables give slightly smaller totals for runoff (1–4 %) at both sites in Vancouver. In London, however, more variation occurs with the different input combinations. In London two of the WFDEI variables gives smaller totals of evaporation (2–9 %) and four variables gives smaller totals of runoff (1–7 %). At all three sites, precipitation has the largest impact on simulated evaporation and runoff when compared to the other meteorological variables (Figure 5). Changing the observed precipitation to WFDEI precipitation increases the modelled cumulative evaporation by 18 % in Vo82, 26 % in Vs09 and 14 % in Lo12 when compared to the control run (Figure 5a, c, e).

Non-gap-filled EC measured evaporation rates for Vs09 (6961 h) and Lo12 (5598 h) allow direct assessment for the hours when observations are available (Figure 6, Table 4). When compared directly to the observed evaporation, the totals are 5 % and 46 % higher in Vs09 and Lo12, respectively, when using the WFDEI precipitation as opposed to the observed forcing data. The RMSEs are 0.0444 mm h⁻¹ for Vs09 and 0.0382 mm h⁻¹ for Lo12 (87 % and 114 % of average hourly observed evaporation, respectively) when compared to direct observations.

As no observed runoff data are available the control runs are used as the reference. For runoff, changing from observed to WFDEI precipitation gives higher values by 27 % in Vo82 and 39 % in Vs09 and a lower value by 7 % in Lo12 (Figure 5b, d, f).

When observed RH and RH derived from WFDEI are compared the correlations and percentages of hourly RMSEs of average hourly observed RH are 0.71 and 15 % in Vo82, 0.78 and 15 % in Vs09 and 0.88 and 9 % in Lo12, respectively. The deviation in RH impacts the modelled evaporation directly. When the observed RH is replaced with RH derived from WFDEI there is a difference in model results of 3–9 % on cumulative evaporation at the three sites. There is an increase of 8 % in Vo82, 3 % in Vs09 and a decrease of 9 % in Lo12 when compared to the control run. The cumulative modelled values underestimate by 17 % in Vs09 relative to the EC observations but overestimate (14 %) in Lo12. The hourly RMSE is 0.0367 mm h⁻¹ in Vs09 and 0.0296 mm h⁻¹ in Lo12 (74 % and 88 % of average hourly evaporation, respectively). For Lo12, the lower values of evaporation when WFDEI RH is used actually balances the higher values due to precipitation and brings the values closer to the modelled evaporation of the control run when all of the WFDEI variables are used to force the model (see Section 3.3). The impact on runoff of changing the observed RH to RH derived from WFDEI is small: a decrease of 2 % in Vo82 and 1 % in Vs09 and an increase of 2 % in Lo12 compared to the control run.

Other WFDEI variables (U , T_a , $K\downarrow$ and p) have minor influence on mean 1 h modelled evaporation and runoff. The difference in total annual evaporation (Vs09, $K\downarrow$) and runoff (Vs09, T_a) are up to 4 % when each measured variable in the forcing is changed to its respective WFDEI variable. Alexander et al.'s (2015) sensitivity study of SUEWS to U , T_a and $K\downarrow$ in Dublin, Ireland found $K\downarrow$ to have the greatest impact but still insignificant. Thus, SUEWS is rather insensitive to minor errors in these meteorological variables at the studied sites. Although RH has a significant effect on the model results it is substantially less than the effect of precipitation, so it is less critical to correct U , T_a , $K\downarrow$, RH, and p in similar matter as precipitation in the WFDEI forcing data.

For SUEWS' performance, realistic precipitation is most critical.

3.2 The effect of bias correction to precipitation

As the WFDEI precipitation clearly overestimates observed precipitation especially in Vancouver (Figure 2), which leads to higher values of evaporation (Figure 5) compared to the control run, the precipitation is bias-corrected with quantile mapping to bring it closer to the observed values.

Effects of varying the BCQM smoothing parameter (a) and moving window (W) for each site on SUEWS modelled evaporation (compared to EC observations) are very small (Table 2). The modelled evaporation is assessed with the root mean square error (RMSE) using hourly data. Varying the smoothing parameter (a) from 0.00 to 0.05 caused the RMSE of the modelled evaporation in Vs09 to vary between 0.0352–0.0353 mm h⁻¹ (69 % of average hourly observed evaporation) and in Lo12 0.0363–0.0364 (108 % of average). The absolute differences of the modelled annual evaporation are 5 % and 31 % of observed annual total evaporation in Vs09 and Lo12, respectively.

Varying the moving window (W) from 21 to 71 days caused the modelled evaporation are very similar to those for a : for Vs09 RMSE varies between 0.0352–0.0355 mm h⁻¹ (69 % of average hourly evaporation) and for Lo12 0.0364–0.0365 mm h⁻¹ (108 % of average). The absolute differences of the modelled annual evaporation are 4–5 % and 31 % of observed annual total evaporation in Vs09 and Lo12, respectively.

Figure 7 shows that the WFDEI daily precipitation distribution is effectively corrected to match the observed distribution of precipitation, except for the most extreme precipitation values where differences are still noticeable. This is probably related to sampling noise in the extreme upper tail of the precipitation distribution and to uncertainties in the extrapolation procedure.

As a result of BCQM correction the annual cumulative precipitation decreased from 1943 to 1479 mm y⁻¹ in Vo82, from 1739 to 1346 mm y⁻¹ in Vs09 and from 859 to 834 mm y⁻¹ in Lo12, bringing it closer to observed precipitation (1215 mm y⁻¹ in Vo82, 1295 mm y⁻¹ in Vs09 and 821 mm y⁻¹ in Lo12) at all three sites. The BCQM correction works reasonably well for Vs09 and Lo12, but there is still quite large overestimation of precipitation left in Vo82. This might be partly due to the differences in the observations. The on-site observations are at 1 h resolution, whereas the long-term observations used for BCQM corrections are at daily resolution and from different locations than the site-specific observations (see Section 2.1). The assessment of biases at daily level using a moving window might introduce artificial biases and differences that might be relatively large when comparing against single year. This underlines the importance of high quality observations for the robust calibration and validation of bias correction methods.

The BCQM corrected precipitation replaced in otherwise observed forcing data decreases the cumulative evaporation by 4–15 % when compared the evaporation given with uncorrected WFDEI precipitation, bringing the values closer to the control run, resulting in higher values of 10 % in Vo82, 11 % in Vs09 and 10 % in Lo12. When compared to the direct observations of evaporation the change of uncorrected WFDEI data to the BCQM corrected precipitation increases the difference by 4 % in Vs09

and decreases the difference by 6 % in Lo12; resulting in underestimation of 9 % and overestimation of 40 %, respectively. However, the hourly RMSE with BCQM corrected precipitation is better than with uncorrected WFDEI precipitation at both sites when compared to the direct observations: 0.0396 mm h⁻¹ in Vs09 and 0.0367 mm h⁻¹ in Lo12 (77 % and 109 % of average hourly evaporation, respectively).

When the BCQM corrected precipitation is used with the observed forcing data the difference in runoff decreases by 0–20 % compared to the difference with uncorrected WFDEI precipitation, resulting in differences of 10 % in Vo82, 19 % in Vs09 and -7 % in Lo12 when compared to the control run.

3.3 Effect of WFDEI forcing data on SUEWS performance

Subsequent model runs use both uncorrected and BCQM corrected WFDEI precipitation while WFDEI values are used for other variables. The simulated evaporation using uncorrected WFDEI as model forcing is larger than for the control run (Figure 5a, c, e) following the overestimated precipitation in WFDEI (Figure 2). The annual cumulative evaporation is 15 % higher in Vo82, 21 % in Vs09 and 6 % in Lo12 compared to the control run with 576 mm y⁻¹ in Vo82, 313 mm y⁻¹ in Vs09 and 391 mm y⁻¹ in Lo12. The difference is much larger at the two Vancouver sites than in Lo12 due to the larger overestimation in precipitation (caused by the close proximity of mountains that affects the grid height of WFDEI, see Section 2.3). Although the BCQM correction to precipitation decreases the bias when compared to the control run, the overestimation of the precipitation is still evident. After the BCQM correction the annual cumulative evaporation with WFDEI forcing data is 8 % higher in Vo82, 6 % in Vs09 and 2 % in Lo12.

The WFDEI forcing data follows closely the runoff of the control run in Lo12 (Figure 5f), but similarly to evaporation, the modelled runoff using uncorrected WFDEI data in Vancouver gives largely higher values compared to the control run (Figure 5b, d). Use of the uncorrected WFDEI gives higher values of the annual cumulative runoff by 26 % in Vo82 and 39 % in Vs09, but gives lower values by 4 % in Lo12, when compared to the control run (1819 mm y⁻¹ in Vo82, 1426 mm y⁻¹ in Vs09 and 577 mm y⁻¹ in Lo12). BCQM correction brings the modelled runoff significantly closer to the reference values in Vancouver resulting in a smaller increase of 8 % in Vo82 and 15 % in Vs09. In Lo12, the difference increases by 1 mm to 26 mm y⁻¹ (4 %) after the BCQM correction. Thus, the relative change caused by the correction is larger in Vancouver than London as the difference is not as great initially when compared to the Vancouver sites.

The directly measured hourly EC evaporation allow for assessment of the modelled evaporation (Figure 6). In Vs09 the modelled cumulative evaporation using the uncorrected WFDEI is very close to the observed value 304 mm y⁻¹ (for the times when observations are available), with an underestimation of 3 %. The BCQM correction increases this underestimation to 15 %. The underestimation is greater (18 %) when measured forcing data are used. Although the underestimation of modelled cumulative evaporation increases, the BCQM correction decreases the hourly RMSE between the measured and modelled evaporation from 0.0398 to 0.0354 mm h⁻¹ (78 % to 69 % of average hourly evaporation, respectively) bringing it very close to the RMSE of the control run (0.0369 mm h⁻¹, 72 % of average). The BCQM correction is not expected to make the model results perfect relative to the observations as differences will remain related to parameterisations within SUEWS. As urban land surface models tend to underestimate vegetative evaporation (Grimmond et al. 2010a, 2011), the larger underestimation is likely linked to the description of evaporation in SUEWS rather than the forcing data itself. In addition to vegetation, the parameterisations of anthropogenic heat flux (Q_F) and storage heat flux (ΔQ_S) impact the turbulent fluxes (Karsisto et al., 2015). Similar values of the latent heat flux RMSE normalized with mean observed values have been found in other studies giving 90–160 % for Vancouver and Los Angeles (Järvi et al., 2011) and 130 % and 70 % for London and Swindon, respectively (Ward et al., 2016b). These results are at the better half of the model performances reported in the urban land surface model inter-comparison study (Grimmond et al., 2011). Deviations between the modelled output and observations are also caused by the other uncorrected meteorological variables.

However, in London the modelled cumulative evaporation with uncorrected WFDEI data is 36 % larger than the measured one (188 mm y⁻¹). The higher modelled values can be explained by the proximity of the River Thames to the EC measurements (Ward et al., 2016b). The surface forcing used in SUEWS is calculated for the source area of the measurements leading to an open water fraction of 14 %. This causes high evaporation rates, but the river itself does not affect the observations as much partly because potential internal boundary layers forming over the water surface do not develop to the height of the EC tower (Kotthaus and Grimmond, 2014b). The BCQM correction improves the model results and the overestimation of the evaporation decreases to 31 %. The modelled evaporation of the control run is closer to the observed values, with an overestimation of 23 %. Although the BCQM correction improves the RMSE, decreasing it from 0.0380 to 0.0363 mm h⁻¹ (113 % to 108 % of average hourly evaporation), with observed forcing the RMSE is only 0.0294 mm h⁻¹ (88 % of average).

4. Conclusions

Urban hydrological and land surface models require fine-scale meteorological data as forcing. However, as these can be locally unavailable for the modelled period and/or at the required resolution, reanalysis may provide the required data for hydrological modelling in urban environments. Although reanalysis data are available for the larger areas in which cities are embedded, some corrections are required to use them as realistic forcing, especially in complex terrain.

Here the WFDEI reanalysis data are assessed as input to an urban atmospheric and hydrologic model (SUEWS). Through sensitivity tests for two sites in Vancouver, Canada, and one site in London, UK, the effect of each meteorological variable and downscaling of precipitation in space and time is assessed. With differences in land cover and weather types the effect of WFDEI

data on SUEWS output can be evaluated in different conditions. In each city, EC measurements of evaporation allow the model results to be assessed.

From the sensitivity tests, it is clear that precipitation has the largest impact on modelled evaporation and runoff, with RH being second. After correction for height, the other WFDEI meteorological variables have only a minor impact on modelled evaporation and runoff and their correction would likely have minimal effect on the model performance. Based on these results, only precipitation is corrected using bias correction in this study.

The WFDEI/GPCC precipitation gives larger values than local observations. The greater difference in Vancouver than London is likely caused by greater changes in orography, particularly the mountains within the reanalysis grid. Deviations of the other WFDEI meteorological variables from observed values are smaller. Overestimation of precipitation causes larger evaporation and runoff values compared to the control run (results using observed forcing data) especially in Vancouver. Following correction of the WFDEI precipitation rates using bias correction with quantile mapping (BCQM), the modelled evaporation and runoff results are more similar to the results of the control run. However, precipitation is overestimated at the studied sites, which is probably explained by the limited amount of observations. This causes sampling errors, particularly in the upper tail of the bias corrected distribution. Also the use of moving window when estimating biases in WFDEI data set can lead to artificial biases.

In order to utilise the BCQM in other cities and sites, long observational time series in the order of 30 years with daily resolution for robust calibration and validation of the mapping are needed. Such observations are likely to exist at least in the vicinity of the city of interest (e.g. from the airports). Despite the BCQM correction method needing parameter tuning, the sensitivity tests in the studied sites show the effect of these parameters being small and fine-tuning of the parameters is not vital. Furthermore, BCQM assumes a stationary bias between the observed and reanalysis precipitation, which may be inappropriate if the calibration data are many years from the application period. When suitable daily precipitation observations exist, BCQM correction decreases the bias in WFDEI precipitation significantly and so improves the usability of the reanalysis data in hydrological modelling when observed forcing data are not available. WFDEI forcing data with BCQM correction applied to the precipitation can be used relatively reliably to model urban hydrology and land surface processes at the local scale, especially if daily-scale temporal variations are not of interest. The correction is equally applicable to downscale future projections of global or regional climate model data for urban areas or to be used with other reanalysis datasets than WFDEI. The correction is also equally applicable for other than urban areas.

As the BCQM correction brings the model results with reanalysis data closer to the control run, it indicates the removal of the first deviation, which is the interest of this study. However, the BCQM correction increases the underestimation of evaporation and does not improve the results assessed by observed evaporation. This is thought to be related to the parameterisation of the model rather than the meteorological data. As the error due to the model parameterisation surpasses the bias in WFDEI data, the parameterisation of surface land models, in addition to downscaling methods, is one of the most critical areas to improve to obtain better results from urban land surface and hydrological models. The BCQM correction in general decreases the higher values of modelled evaporation (4–15 %) and the difference of modelled runoff (0–24 %) when compared to the control run, but also brings the hourly RMSE of the modelled evaporation closer to the EC observations. Thus, the BCQM correction decreases the hourly RMSE and the bias of SUEWS' results when compared to the control run at all sites indicating that scaling precipitation to an urban area is highly relevant.

Table 1. Characteristics of the study sites. Data from Järvi et al. (2011) and Ward et al. (2016b).

City	Vancouver	Sunset	London
	Oakridge		Westminster
Year	1982	2009	2012
DOY	22–365	1–365	1–366
Code	Vo82	Vs09	Lo12
Location	49°13'29"N, 123°7'57"W	49°13'26"N, 123°5'6"W	51°30'42"N, 0°6'59"W
A (ha)	21	78	78.5
f_{bldg}	0.19	0.23	0.38
f_{pav}	0.25	0.45	0.43
f_{evergr}	0.04	0.03	0.00
f_{dec}	0.08	0.09	0.02
f_{water}	0.00	0.00	0.14
f_{grass}	0.44	0.2	0.03
$f_{irrgrass}$	0.75	0.9	0.00
f_{aut}	0.05	0.01	0.00
p_{pop} (in ha^{-1})	20.5	64.1	310.4
T_{zone}	GMT-8	GMT-8	GMT
z_h (m)	7	5.5	22.0
z_{hv} (m)	7	7.1	13.1

Year: year of sensitivity tests model run, DOY: day of the year, Code: short name for the site, A: modelled area, f_{bldg} : plan area fraction of buildings, f_{pav} : plan area fraction of paved surfaces, f_{evergr} : plan area fraction of evergreen trees and shrubs, f_{dec} : plan area fraction of deciduous trees and shrubs, f_{water} : plan area fraction of open water, f_{grass} : plan area fraction of grass, $f_{irrgrass}$: fraction of grass that is irrigated, f_{aut} : fraction of automatic irrigation, p_{pop} : the population density, T_{zone} : time zone, z_h and z_{hv} : mean building and vegetation height.

Table 2. Metrics obtained from comparing 60 min measured and modelled evaporation for Vancouver-Sunset in 2009 (Vs09, n=6961) and London in 2012 (Lo12, n=5598) with different smoothing parameter values (a , eqn 2) and moving windows (W , eqn 1) of the BCQM correction of precipitation: root mean square error (RMSE, $mm\ h^{-1}$), mean absolute difference (MAE, $mm\ h^{-1}$) and absolute difference of cumulative values (ΔE , $mm\ y^{-1}$).

Vs09				Lo12		
a	RMSE	MAE	ΔE	RMSE	MAE	ΔE

(a) Vancouver, Canada

(b) London, UK

Figure 1. Map of a) Vancouver, Canada (Mapzen, 2017) and b) London, UK (Mapzen, 2017) showing locations of the study sites (Vancouver-Oakridge (Vo82), Vancouver-Sunset (Vs09) and King's College (Lo12)) and precipitation monitoring sites (Vancouver International Airport, Hollyburn Mountain, Grouse Mountain, South Richmond, St James's Park and Hampton W WKS). Latitude and longitude lines are also locations of WFDEI grid boundaries.

Figure 2. Normal (1981–2010) monthly precipitation (left-axis) and 2 m daily temperature (T_a) (right-axis) recorded at (a) Vancouver International Airport (Environment Canada, 2015) and (b) Hampton W WKS (lat: 51.4119 N, lon: 0.37809 W, station number: 711 Met Office 2015) and the WFDEI data (Weedon et al., 2014) for the grid these sites are located in.

Figure 3. WFDEI incoming solar radiation (K_{\downarrow}) versus observed K_{\downarrow} at a) Vancouver-Oakridge in 1982 (Vo82), b) Vancouver-Sunset in 2009 (Vs09) and c) London in 2012 (Lo12).

Figure 4. Flow diagram of bias correction with quantile mapping (BCQM).

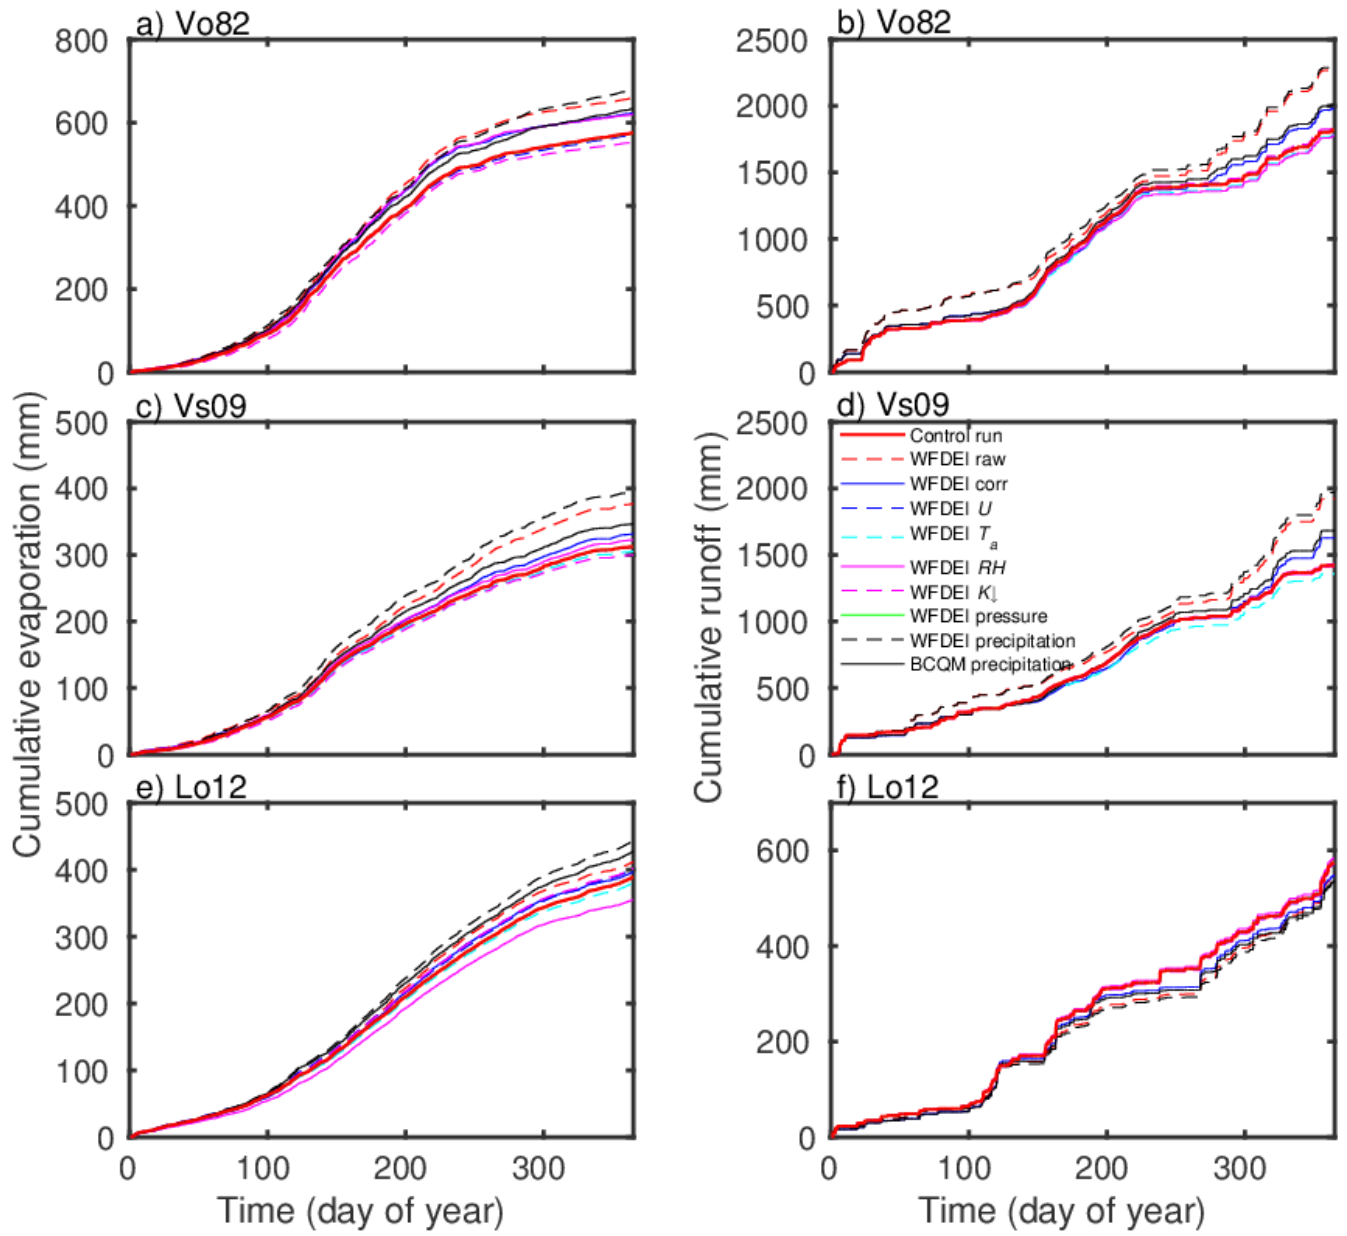

Figure 5. Modelled cumulative (a, c, e) evaporation and (b, d, f) runoff for (a, b) Vancouver-Oakridge in 1982 (Vo82), for (c, d) Vancouver-Sunset 2009 and for (e, f) London in 2012 (Lo12) using observed forcing data (control run), uncorrected forcing data (WFDEI raw), precipitation corrected WFDEI data (WFDEI corr). The sensitivity tests with one measured meteorological variable modified in each run to the reanalysis forcing data (e.g. BCQM precipitation: has corrected reanalysis precipitation with otherwise observed forcing data). Note different scales of the y-axes.

Figure 6. Observed and modelled evaporation (a, b) annual total (a) Vancouver-Sunset in 2009 (Vs09, $n=6961$) and (b) London in 2012 (Lo12, $n=5598$) for all hours with direct observations of evaporation using different model forcing data (see Figure 5); (c, d) RMSE of hourly values. The ranking number from smallest to largest value is shown under the bars.

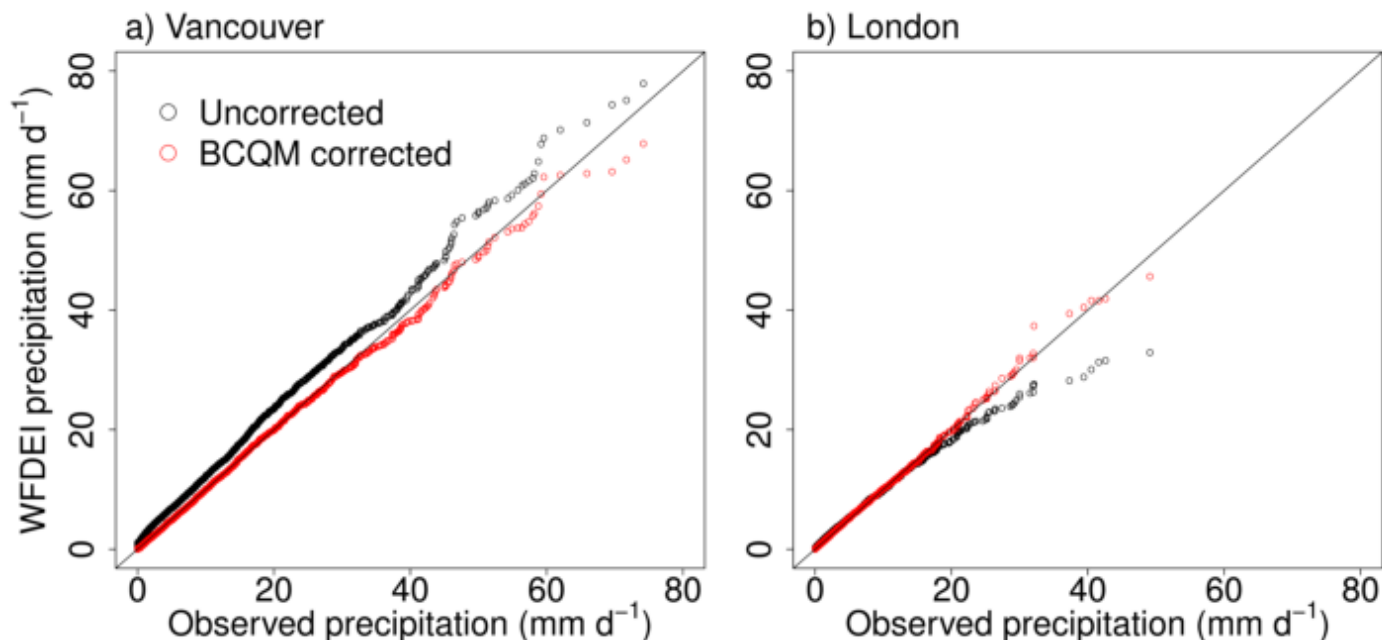

Figure 7. Quantile-quantile plots for uncorrected WFDEI precipitation (black) for 1979–2012 in a) Vancouver and b) London and BCQM corrected precipitation (red) versus observed precipitation (1990–2008 in Vancouver and 1980–2008 in London). Both Vancouver sites use the WFDEI forcing data from the same grid cell.
