Abstract

Insects play a key role in the regulation and dynamics of many ecosystem services (ES). However, this role is often assumed, with limited or no experimental quantification of its real value. We examine publication trends in the research on ES provided by insects, ascertaining which ES and taxa were more intensively investigated, and with which methodological approaches, with particular emphasis on experimental approaches. We performed a systematic literature search to identify which ES have been attributed to insects. Then we classified the references retrieved according to the ES, taxonomic group and ecosystem studied, as well as to the method applied to quantify the ES (in four categories: no quantification, proxies, direct quantification and experiments). Pollination, biological control, food provisioning and recycling organic matter are the most studied ES. However, the majority of papers do not specify the ES under consideration, and from those that do it, most do not quantify the ES provided. From the rest, a large number of publications use proxies as indicators for ES, assuming or inferring their provision through indirect measurements such as species abundances, species richness, diversity indices, species density or the number of functional groups. Pollinators, predators, parasitoids, herbivores and decomposers are the most studied functional groups, while Hymenoptera, Coleoptera and Diptera are the most studied taxa. Experimental studies are relatively scarce and they mainly focus on biological control, pollination, and decomposition performed in agroecosystems. These results suggest that our current knowledge on the ES provided by insects is relatively scarce and biased, and shows obvious gaps in the least-studied functional and taxonomic groups. An ambitious research agenda to improve the empirical and experimental evidence of the role played by insects in ES provision is essential to fully assess synergies between functional ecology and biodiversity conservation.
**Keywords:** Biological control; Coleoptera; Decomposition; Ecosystem functions; Experimental research; Hymenoptera; Insecta; Nutrient cycling; Pest regulation; Pollination.

**Introduction**

Understanding, valuing, quantifying and ensuring the provision of ecosystem services (ES) under current global changes have become increasingly important during the last two decades (Turner et al., 2007, Seppelt et al., 2011 and Díaz et al., 2013). ES can be defined as the beneficial functions and goods that humans obtain from ecosystems, that support directly or indirectly their quality of life (Harrington et al., 2010 and Díaz et al., 2015). These services are critical for human welfare (Daily et al., 2000), since they include, amongst others, the provision of food and water, the regulation of floods, diseases and climate, the control of organic matter decomposition and nutrient cycling, the suppression of pests, and the cultural services associated with recreation or education (Millennium Ecosystem Assessment, 2003 and Díaz et al., 2015). The definition and interpretation of ES has varied considerably in the literature over the years (De Groot et al., 2002, Harrington et al., 2010 and Spangenberg et al., 2014), and this concept is often confounded with related terms such as “ecosystem functions” and “ecosystem goods” (Millennium Ecosystem Assessment, 2003 and Díaz et al., 2015). Ecosystem functions refer to all biogeochemical characteristics of ecosystems (including the structures and processes that may arise as emergent properties), regardless of whether they have a value for, or benefit, humans (Spangenberg et al., 2014). Whereas ecosystem goods correspond to the products of ecosystem services that can be traded by humans through either perception, expectations, experience, use or consumption (Díaz et al., 2015).

Insects are the largest and most diverse group in the animal kingdom. They are key
components in the provision, regulation and dynamics of many ecosystem services (referred as insect ES herein; Weisser & Siemann, 2004 and Schowalter, 2013). Insects are potentially involved in the four broad types of services defined by the Millennium Ecosystem Assessment (2003): (i) provisioning services, that correspond to material or energy outputs from the ecosystems; (ii) supporting services, that allow the maintenance of other ES; (iii) regulating services, that regulate the processes and structure of ecosystems; and iv) cultural services, that do not provide material benefits but have an educational, spiritual and/or aesthetic value (GEO4, 2007 and Prather et al., 2013). Previous efforts to assign monetary values to several ES provided by insects usually underestimated the value of these animals to our economies and quality of life (Beynon et al., 2015). Still, insects provide ES worth at least $57 billion per year in the United States alone (Losey & Vaughan, 2006), and insect pollination may have an economic value of $235 to 577 billion per year worldwide (IPBES, 2016).

A realistic assessment of the contribution of natural resources and biodiversity for the delivery and maintenance of ES depends on having accurate information and a clear understanding of the processes involved in the provision of those services (Haines-Young & Potschin, 2010). There is a general lack of knowledge on the functional roles played by most species in nature (i.e. the so-called Raunkiaeran Shortfall; Hortal et al., 2015). This is particularly important when assessing the value of insect ES. Despite their enormous diversity, insects are often under-represented in ecosystem studies, so their contribution to ecosystem functioning has been comparatively less investigated (Schowalter, 2016). As a consequence, we often lack a comprehensive understanding of the role of insects in many ecosystem processes that underlie ES. Although many efforts to quantify insect ES have been developed in the last decade (e.g. Prather et al., 2013 and Boerema et al., 2017), they
particularly focused on a subset of either functional or taxonomic groups, such as pollinating bees or dung beetles.

Current knowledge on the ES provided by insects has usually been obtained from a variety of methodological approaches, ranging from field observations to manipulative controlled experiments, even though such relationship is often simply assumed (e.g. Philpott & Armbrecht, 2006 and Allsopp et al., 2008). Thus, assessment of insect ES includes a wide variety of approaches such as opportunistic field observations, expert opinions or estimates, assumptions or inferences made from proxies (e.g. species richness, total abundance, morphological traits), estimates inferred from trait values and empirical data obtained from field and/or microcosm experiments that may or may not have been specifically designed to quantify the real ES provision in the first place. These approaches also differ widely in their replicability, accuracy, and applicability of their outputs, direct relevancy to the ES itself, as well as in their costs in terms of time and resources. Further, while they may allow inferring which insects provide which ES, proxies might not be appropriate to reveal the mechanisms linking specific traits to particular ecosystem functions or services. A better quantification of the specific relationship between ES and specific traits provides a potentially useful link to the wide-scale prediction of ES (de Bello et al., 2010), although this information is limited to a few groups and ecosystems (see Hortal et al., 2015). This contrasts with greenhouse and cage experiments performed on individual species or simple communities, which enable either maintaining a tighter control of the environmental conditions or subjecting the object of study to well-defined treatments, or both (Lähteenmäki et al., 2015). This allows establishing –and measuring– direct links between given ES and particular individual(s), trait values, and functional components of biodiversity (e.g. Dias et al., 2013 and Bílá et al., 2014), while revealing mechanisms behind the relationship between biodiversity and ES. However, these
types of studies present several disadvantages, as they can be expensive and laborious. Further, synergies and/or antagonistic effects are difficult to control, and their findings might not be relevant or realistic when up-scaling to real-world conditions and/or when they are extrapolated to a different taxa from the model species.

We examine the general trends in published research on ES provided by insects, to provide an overview of the overall quality and extent of the current state-of-the-art on this topic. To do this, we conduct a systematic literature search, identifying which specific services have been attributed to insects, which methodological approaches have been applied to describe and quantify these ES over time, and whether there are any important gaps in current knowledge. In particular, we seek to answer the following questions: (i) Which insect ES have been studied? (ii) What type of methodological approaches have been used for their study of these ES? (iii) Which functional and taxonomic groups of insects have been investigated in this context? and, (iv) Which ecosystems have been monitored experimentally for insect ES?

**Materials and methods**

We performed a literature search using different online platforms to identify articles dealing with insect ES that were published during the last six decades (1956–2016, time interval preselected by default by some of the online platforms). Firstly, we conducted bibliographic queries in the ISI Web of Knowledge (WOK) and Scopus using the keyword string “(ecosystem* service* OR ecosystem* function* AND insect*)”, looking for matches in the title, abstract and/or keywords. In addition, we used the same keywords to retrieve articles from the group associated with “ecosystem services and insects” in ResearchGate (www.researchgate.net, one group: ecosystem service insects) and ACADEMIA
(www.academia.edu, three groups: ecosystem services, ecosystem service and ecosystem functions). Since the terms “ecosystem services” and “ecosystem functions” are often used very loosely in the literature, we widened our search by using both terms and thereafter discarded those references that were not clearly related to any ES. Therefore, from the initial search (updated on 30th December 2016) we retrieved 8,424 records (WOK: 2,348, Scopus: 2,859, ResearchGate: 200, Academia: 3,017). We then eliminated conference papers, articles in press, duplicate records (i.e. articles that appeared more than once in the different search engines, or in the same platform due to typographical errors) and finally, all those references not related to any ES or insect group. The finally selected records included 913 papers that provided ES estimates.

The following information was retrieved from each selected publication: author(s); year of publication; journal; method used for quantifying each ES in four categories: not quantified, proxies, directly quantified, and experiments (Table 1); trophic group(s); taxonomic group(s) (order and superfamily or family); ES studied (specific ES or ES in general); and any relevant additional observation as notes. To keep consistency with the literature, we used the term ‘biological control’ to refer to the most-adequate term “pest and pathogen suppression” (that includes both human-controlled and ‘natural’ regulation of pest populations). In addition, the type of ecosystem investigated and the location of the study were recorded for the experimental studies.

This type of literature search has several limitations that were considered when analyzing the data and interpreting the results. Firstly, the search may miss some relevant papers, simply because the title, abstract or keywords did not contain the keywords searched. In fact, our literature search was biased towards publications specifically referring to insect groups (i.e. studies that included the word ‘insects’ only), which could result in missing some
papers that focus on particular species (e.g. *Apis mellifera*), functional groups (e.g. pollinators) or larger groups of invertebrates that also include insects. Secondly, the approach used here might have overlooked publications that refer to a particular ecosystem service by its name (e.g. pollination) without quoting the words “ecosystem services” *per se* in their abstract or keywords. These limitations have been previously identified by other authors using similar search approaches (e.g. Prather et al., 2013). Thirdly, the term “ecosystem service” is fairly recent, and its use was not common prior to the 1990s, so some older publications addressing insect ES may not have been detected by our search. Finally, we may have failed to include some works that were not indexed by the platforms used here. However, and despite these problems, we believe that the data retrieved gives us enough relevant information to examine general trends in insect ES research and to identify knowledge gaps on the topic that could help us to develop future research strategies to better evaluate the ES provided by insects.

**Results**

Our search retrieved 913 articles, published from 1989 to 2016, with relevant information on the ecosystem services provided by insects (see Appendix A). There were no papers before 1989 with the specific keyword string used for our search. These articles show an exponentially increasing trend in the number of insect ES studies over time (Fig. 1). Pollination, biological control, food provisioning, and recycling organic matter are the most well studied ES (Fig. 2A), although the role of insects has been investigated for many others, including a number of services that were not included in former reviews on insect ES (Table 2). Remarkably, 20% of the publications (N=184) mention ES in general without referring to any specific service (Fig. 2A), without clarifying the role that the investigated insect groups or
species performed to deliver these services. ES of high socio-economic relevancy, such as pollination and biological control in agricultural ecosystems, are both the most commonly studied and those with the highest proportion of experimental data supporting the link between the studied insects and the service provided (Fig. 2B). Indeed, there is a remarkable similarity between the proportions of studies focused on these two ES and nutrient cycling, and the functional groups performing these services (i.e., pollinators, predators and parasitoids, and decomposers, respectively; compare Figs. 2A and 2C).

The majority of insect ES literature does not include a quantification of the actual level or extent of the ES studied: categories not quantified and proxies sum up 69.6% of all papers (N=635; Fig. 3A). These studies are not restricted to those not specifying the ES under consideration, but rather extend to all types of services (Fig. 2B). Strikingly, almost half of the publications retrieved by our search used proxies as indicators for ES (46.8%, N=427; Fig. 3A), particularly for pollination and non-specified biological control services (Fig. 2B). Less than a third of studies actually quantify insect ES either directly or through experiments (N=278, 30.4%), although the proportion of these two kinds of studies together has increased steadily during the last 15 years (Fig. 3B). Strikingly, most of them make direct measures without any experimental manipulation (N=222, 24.3% of all papers), whereas experimental studies undertaken either in the laboratory or in the field represented only 6.1% (N=56) of the total number of publications (Fig. 3A; see Appendix B). Pollination, biological control and nutrient cycling were the ES most studied using experiments (Fig. 2B).

As identified above, insect ES are most commonly studied through proxies. These proxies are typically species abundance, species richness and, to a less extent, ecological diversity indices such as Simpson or Shannon, among others (sometimes referred to as alpha diversity, but see Magurran, 2004) (Fig. 3C). However, many other proxies have been used in
the literature, including species density, the number of functional groups, visitation rates, network complexity and modularity, functional traits (e.g. body size/biomass, behavioral traits, colony density and health, etc.) and associated measures of functional diversity, species composition, beta diversity, niche overlap or endemcity, among others. Very few studies corroborated the existence of a direct link between the proxy and the functional aspect that was intended to represent, at the studied geographical scales and/or for a specific taxonomic or trophic group (exceptions being, e.g., Arnan et al., 2013 and Rader et al., 2014).

Pollinators, predators of pests, parasitoids, herbivores and decomposers (especially dung beetles) were the most studied functional groups (Fig. 2C), together with some charismatic and/or easy to identify groups such as ground beetles or bumblebees. The order Hymenoptera –that includes many pollinators (particularly bees), parasitoids (commonly used for biological control), predators and decomposers (such as ants)– has been the most studied taxonomic group, followed by Coleoptera and Diptera (Fig. 4A). In fact, hymenopterans have been comparatively overstudied if we take into account the total number of described species (Fig. 5). At a finer taxonomic level, several superfamilies or families also emerge as being highly studied subjects, including Apoidea (particularly Apidae), Formicidae and Braconidae belonging to Hymenoptera; Carabidae, Coccinellidae and Scarabaeidae within Coleoptera; Syrphidae among Diptera and several families of termites from Blattodea (Fig. 4C).

The services most studied using experimental approaches are biological control, pollination and decomposition (see Appendix B). Thus, the links with ES have been more often quantified in experimental studies for Hymenoptera and Coleoptera (Fig. 4B). Most experimental evidence on insect ES comes from USA and Europe – in particular Switzerland, Germany and Sweden, although a few studies have also been performed in developing countries such as Costa Rica, Mexico, Philippines, Tanzania, Indonesia, Kenya and Argentina
(see Appendix B). The ecosystems most commonly studied experimentally were agroecosystems, which included a long list of different types of crops (e.g. almonds, cabbage, cacao, cereals, coffee, rice, potato, wheat, etc.). The services provided by insects in grasslands and, to a lesser extent, forests, savannas, wetlands or lakes have also received some (though much less) attention (see Appendix B).

Discussion

Research interest on the ecosystem services provided by insects grew during the last decade (Stout & Finn, 2015, and references therein). The increase in the number of papers published on this topic mirrors the pattern described by Hallouin et al. (2016) for ES in general, and reflects the expanding significance of identifying, analyzing, conserving, and managing ES under the global changes that characterize the Anthropocene. This general interest has reached entomological research, resulting in a clear increase in the number of studies focusing on insect ES (compare our Table 2 with the list provided by GEO4, 2007 or Turner et al., 2007). Despite such recent work, the services provided by insects still remain relatively understudied compared to other groups. Insects comprise 49.9% of the 1’656,025 accepted species currently included in the Catalogue of Life (accessed on 23rd December 2016; Roskov et al., 2017). However, a quick search in Scopus (using “ecosystem service*” AND [insect* OR coleop* OR hymenop* OR lepidop* OR dipter* OR bees OR beetle*], 26th January 2017) produced 1,102 documents on insect ES out of 16,476 for ES in general. That is, about 6.7% of the total research output on ES is devoted to these invertebrates making up half of known diversity, containing species and trophic groups with unique roles in ES provision. This comparatively low level of knowledge arises despite the fact that, in many cases, it is likely that the majority of particular ES are supported by a relatively small number
of invertebrate species (e.g. for pollination, Klein et al., 2015).

Remarkably, the majority of the studies on insect ES published so far are descriptive, either making no quantification of the ES or using proxies to indirectly link species and/or groups to particular ES, even for the better-studied groups such as bees (e.g. Eardley, 2000, Morandin et al., 2007 and Kimoto et al., 2012). Experimental studies and direct ES quantifications have become more common in recent years, but still account for a small proportion of published studies. Experiments are therefore needed to ascertain in detail which species or functional groups provide a particular service, and which mechanisms and aspects of biodiversity are behind the provision of specific ES (e.g. Slade et al., 2007, de Bello et al., 2010 and Ibanez et al., 2013). A better understanding of the links between insect diversity, insect behavior, and ES provisioning is also needed (Schmitz, 2008 and Brosi & Briggs, 2013). Considering that most information on insect ES comes from studies using proxies rather than direct quantifications or experiments, it is likely that most current knowledge on these services holds a high degree of uncertainty, for it is based only on estimates rather than quantitative assessments (Boerema et al., 2017). This lack of robust quantitative data can indeed hamper the assessment of global change effects, preventing us from identifying and/or quantifying the impacts of environmental changes on ES, and therefore making difficult to design adequate actions to mitigate them.

*From proxies to experiments*

Further analysis is required to determine why proxies are preferred to direct service quantifications and/or experiments in ES research, both in general and in the particular case of insects. Some ES, such as nutrient cycling or soil nutrient regulation, are difficult to quantify and/or require laborious, expensive and time-consuming work, making the use of proxies
more attractive (e.g. Hoffman et al., 1996 and Palin et al., 2011). In fact, there are no well-established standardized ways of quantifying the value for some ES, such as provision of nursery habitats, cultural, educational and pharmaceutical services, tourism, and urban quality of life (see Nallakumar, 2003 and Choosai et al., 2009). Quantifying the value of a number of ES presents important methodological difficulties, such as the spatial redistribution and accumulation of soil nutrients, seed dispersal and germination, or soil removal (see Folgarait, 1998, Pringle et al., 2010 and Wu et al., 2010). One big challenge to ES field experimentation is excluding a particular taxon from the system to measure the effects of different taxa on the ES of interest. This has strained efforts to accurately quantify the contribution of insects to the decomposition of both litter (Kampichler & Bruckner, 2009) and wood (Ulyshen & Wagner, 2013), and to nitrogen cycling in grasslands (Risch et al., 2015). Some success has been, however, achieved with dung beetles (e.g. Slade et al., 2007, Beynon et al., 2012, Griffiths et al., 2015, Lähteenmäki et al., 2015 and Slade & Roslin 2016).

The most commonly used proxies for ES are species richness and species abundance. However, these two metrics could provide limited information on service delivery if they do not adequately capture the uneven contributions of different taxa to an ES (e.g. Klein et al., 2015). The relationship between taxonomic diversity and ecosystem function is often context-dependent (Tylianakis et al., 2008), and it is not uncommon for the effects of a single taxon on a particular service to eclipse those of all other species in a community (e.g. Straub & Snyder, 2006 and Klein et al., 2015). Studies addressing the importance of insects for wood decomposition, for example, have shown termites to consume by far more wood than all other insects combined (Ulyshen et al., 2014). Indeed, an increasing number of studies show the importance of considering functional aspects of biodiversity in improving our understanding of the relationships between proxies and ES (Díaz et al., 2013, Lavorel et al., 2013, Moretti et
al., 2013, Harrison et al., 2014 and Wood et al., 2015).

Metrics related to functional diversity or attributes (i.e. traits) that affect an ES (sensu Violle et al., 2007 and Díaz et al., 2013) may be more informative than those related to total abundance or taxonomic richness (Lavorel et al., 2013). Trait-based metrics can take into consideration that different species (and individuals) have different effects on the ecosystem, and assume that there may also exist some complementarity among species’ functioning (Hoehn et al., 2008). Indeed, it has been argued that trait diversity at the community level is one of the key factors governing ecosystem properties (Hooper et al., 2005), sometimes exceeding species richness in importance (Hoehn et al., 2008). However, a proper use of traits to link diversity and ES requires good knowledge on which traits are associated with a particular ecosystem function and/or service, the intraspecific variability of these traits, under what environmental conditions are those functional traits more important, and which component of the distribution of trait values within communities is most appropriate to account for service provision (i.e. mean or variance; e.g. Ricotta & Moretti, 2011, Dias et al., 2013 and Griffiths et al., 2016a).

Unfortunately, data on traits and knowledge on how these traits translate into ES are limited (Hortal et al., 2015), at least at the spatial scales relevant to the study of ES. This shortfall is even more acute in insects and other soil invertebrates (but see e.g. Ibanez, 2012 or Martins et al., 2015). An adequate selection of traits genuinely related with the studied service could provide a mechanistic understanding of the role of insects in ES provision, and will nonetheless have the greatest potential to infer ES delivery (e.g. Woodcock et al., 2013 and Griffiths et al., 2016b). However, many times, the traits used for ES analyses are chosen based on either readily-available trait data, or on traits used by former studies, rather than on a functional hypothesis linking traits, ecosystem functions, and their associated services. This
can result in a consistent bias towards using small subsets of traits, some of which could have little value for particular functions or services. Even in those few cases where the traits genuinely related with the studied service have been identified, their data are typically limited to a handful of species, as their measurement is often labour intensive. Therefore to improve the use of trait-based proxies for insect ES research further work is needed to provide experimental evidence on the relationship between trait variation and service provision. Initiatives to provide standardized measures of traits across terrestrial invertebrates and their effect on ecological functioning –such as the invertebrate trait handbook proposed by Moretti et al. (2016)– are key for the advance of insect ES research.

*Functional and taxonomic biases*

The biases in insect ES research are both functional and taxonomic; not only some services are more studied than others, but also some groups are more studied than others. Indeed, the most-studied ecosystems are croplands and consequently, the focus is placed on those ES that have a larger impact on the goods we receive from these managed ecosystems such as pollination and biological control, two services with high economic impacts (Losey & Vaughan, 2006). These two services are also the ones that have been more studied using experimental approaches, together with nutrient cycling. Hence, a good example of why biases are often functional rather than taxonomic is the high proportion of papers that have studied pollination. These often analyze more than one insect group or the whole community of pollinators, including Hymenoptera (predominantly Apoidea and some additional families), Diptera (Syrphidae) and Lepidoptera (e.g. Gardiner et al., 2010, and Lundin et al., 2013). This contrasts with the research on many ES of less obvious and/or indirect economic importance, such as dung removal, seed dispersal, soil aeration, pest control or soil water infiltration.
These studies are typically constrained to a single trophic group and/or a single taxonomic group, hence providing very little information on the whole-community responses and/or the interactions between ecosystem services, functional and/or taxonomic groups. In addition, there is an evident bias in the literature we reviewed towards those groups that can be easily studied (e.g. towards above- vs. below-ground organisms), have larger body sizes (e.g. butterflies vs. flies), are readily identifiable (e.g. Carabidae are more often studied than the taxonomically complex Staphylinidae), or are more charismatic (e.g. bumblebees compared with flies).

The publications that study multiple ES rarely focus on a single group of insects (e.g. Klein et al., 2006 and Campbell et al., 2012; but see Slade & Roslin, 2016). In fact, many recent articles considering several taxonomic groups have investigated how their combined responses to different stressors interact with service provision, such as biological control or pollination (e.g. Mody et al., 2011, Caballero-Lopez et al., 2012 and Stanley & Stout, 2013). However, very few studies have analyzed the possible range of interactions (from synergies to antagonistic or trade-offs) between two or more ES within a specific network or for the whole ecosystem. A significant exception to this lack of knowledge are those studies investigating the interaction between different groups of pollinators and those describing the regulating services provided by other elements of the ecological network, such as pest control provided by predators and parasitoids, or the effects of herbivores on the pollinated plants (e.g. Morandin et al., 2007, Hegland et al., 2010, and). Indeed, current knowledge indicates that these regulatory relationships usually affect network dynamics and hence, the supporting ES provided by insects in a negative way (Badano & Vergara, 2011).

There are few quantitative assessments of the ES provided by several functional and taxonomic groups, either from experiments or from indirect quantifications. Our bibliographic
search failed to find any information for several key functional groups, such as rhyzophagous insects, some decomposers and many symbionts and kleptoparasites. Similarly, very few studies were found concerning several small insect Orders, such as Ephemeroptera, Plecoptera or Neuroptera. Therefore, the design of our review, which focused on describing publication trends rather than assessing knowledge gaps in a conceptual map, might have prevented us from resolving whether these groups are underrepresented in ES research, if they actually provide few services of minor importance, or whether the lack of general knowledge on their ecology and systematics is the main cause of their misrepresentation. The key ecological roles played by some of them in freshwater ecosystems (e.g. litter decomposition) suggests that many of these groups are likely to have a very significant role in the provision of many ES (Macadam & Stockan, 2015). Our bibliographic survey also pinpoints other biases that are common in biodiversity knowledge, such as the lack of data for many geographical areas and ecosystem types. Knowledge on all aspects of biodiversity is typically concentrated in northern temperate regions, particularly Europe and North America (Hortal et al., 2015). This widespread bias is also evident in the published work on insect ES; very little is known about the services provided by insects in agroecosystems outside these two regions, with the exception of some limited work in tropical plantations (mostly coffee and trees) or savannas. However, the sheer lack of knowledge on insect ES throughout most of the world’s ecosystems makes more developed analyses on geographical and ecological biases premature.

A cautionary note on insect disservices

It is important to highlight that we did not include in our analysis papers studying disservices by insects for two main reasons. First, the goal of this paper was to characterize the trends in insect ES research and, in particular, how much current information comes from
experimental evidence. Second, the study of insect disservices is a vast topic that would not be easy to embrace using literature searches, and that definitively requires a separate analysis. However, the line that separates an ES from a disservice is sometimes very thin. In fact, in some cases, the same ecological function can be qualified as service or disservice depending on the perspective. While the effects of many foliage or root feeders might often be considered as disservices, they do provide regulating services by controlling the populations of both weeds and certain pests through herbivory and/or competitive exclusion, respectively or by helping to maintain populations of generalist predators and parasitoids (e.g. Martin et al., 2010, Evans et al., 2011 and Eckberg et al., 2014). Herbivores also influence nutrient cycles and can contribute to soil fertility and enhance primary production (Belovsky & Slade, 2000). Also, bark and wood boring insects, create suitable habitats for other insects (e.g. Zuo et al., 2016) and have been shown to facilitate colonization by fungi, thus indirectly accelerating the decomposition of woody debris (Strid et al., 2014 and Ulyshen et al., 2016). It is therefore important to understand which ecological functions performed by herbivores can in fact result in regulating services, and how they interact with supporting and provisioning services.

As a consequence of this, during our bibliographic search we found some articles that evaluated or studied ecosystem disservices, related to three main topics: (i) damage of agricultural crops by herbivores (e.g. Hiltpold et al., 2013 and Dale & Frank, 2014); (ii) damage to wood plantations by xylophagous insects (e.g. DeSantis et al., 2013 and Reich et al., 2014); and (iii) harmful effects on human health by hematophagous insects (e.g. Sommerfeld & Kroeger, 2013 and Muturi et al., 2014). Some of these studies were not discarded from our final list because they refer to ecological functions that can be classified either as services or disservices.
Concluding remarks

Knowledge on the ecosystem services provided by insects is relatively scarce and biased. This occurs despite the fundamental importance of the ecological functions they perform for the maintenance of ecosystem functioning and their links to human well-being. Part of the reason behind the poor knowledge on insect ES comes from the tradition of considering insects as providing mainly disservices to humanity, through pest and parasite outbreaks. However, given the sheer diversity of insects and their key ecological role in all terrestrial and freshwater ecosystems, it is extremely likely that the economic and non-economic benefits provided by this group through many ES may be much larger than the damage and disservices they provide even in some specific areas such as crop production. Indeed, the value of some ES provided by insects, such as pollination, is widely accepted in financial, food security and health terms. Valuing these services can therefore be a good way to stimulate and promote research into them – through increasing financial support and societal engagement.

It is therefore key to gain an increased understanding of the role played by insects in ES delivery. This requires combining the efforts of ES researchers (including ecologists, entomologists, economist and social scientists) to identify direct links between insect species and the ES they provide, either through field observations or experiments. A good map of our current knowledge could help defining further needs in insect ES research. Our work provides a review of current knowledge in the area and identifies obvious gaps in the less-studied functional and taxonomic groups. Moreover, we also highlight the existence of knowledge gaps in the research of some ES that either have a lower direct economic value, or their study poses important methodological challenges. However, the nature of our analyses prevents us
from obtaining a complete overview of what is actually known and a full distribution of the knowledge gaps, since we characterize publication trends rather than the level of completeness, accuracy and usefulness of the knowledge on each ES, ecosystem and/or insect group.

A clear shortfall in current knowledge is the lack of high-quality quantifications of ES delivery (Boerema et al., 2017), either directly in the field or through experiments. Ideally, such information should be obtained by adopting a robust and cohesive common framework for insect ES research, which clearly separates ES from ecological functions, which have been more commonly studied for insects. Many studies use the term ES very loosely; actually, some consider ecological functions of non-human value as services too. A conceptual and methodological framework that clearly links the study of functions with the quantification of the delivery of services can help to increase the research impact of ES for insects in general, and for many seldom-studied groups in particular. This framework should consider the interactions and trade-offs among the services provided by different insect groups, allowing us to also identify and measure the services provided by less diverse insect orders. A first step in the implementation of such framework is certainly to quantify insect ES provision in the field, but in the mean time, it is necessary to implement a combination of laboratory and field experiments. While the use of controlled microcosms can provide accurate information, manipulative field experiments are more realistic since they take into account the interacting environmental factors. Obtaining accurate and comprehensive information on the ES provided by insects therefore requires joining efforts in implementing such an ambitious research program that combines empirical and experimental evidence.

Acknowledgements
We want to thank Teja Tscharntke and Timothy D. Schowalter for encouraging us to carrying forward our initial bibliographic survey into this review, and for inviting us to submit this manuscript to the special issue on insect ecosystem services. JAN has been supported by a Colombian COLCIENCIAS PhD scholarship. DAL was supported by the NSF Long-term Ecological Research Program (DEB 1027253) at the Kellogg Biological Station and by Michigan State University AgBioResearch. SGP was supported by the European Community's Seventh Framework Programme under grant agreement no 311781, LIBERATION Project (www.fp7liberation.eu). BAW was supported by the NERC/BBSRC funded ASSIST project (NE/N018125/1). AMCS by a Juan de la Cierva Fellowship (IJCIC-2014-19502) funded by the Spanish ‘Ministerio de Economía y Competitividad’.

Author contributions: JAN, JH and AMCS designed research; JAN performed research; all authors discussed the results; JAN, JH and AMCS wrote the paper, with all authors; all authors approved the last version of the manuscript.

Appendix A and B. Supplementary data

Supplementary data associated with this article can be found, in the online version, at XXXXX.

Table 1. Categories of quantification of the ecosystem services (ES) provided by insects used to classify the studies retrieved by our literature review.

<table>
<thead>
<tr>
<th>Quantification category</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>Not quantified</td>
<td>Assume the relationship between ES and the studied taxonomic or functional group following the criteria of experts. There is no attempt to measure the service, neither directly nor indirectly.</td>
<td>Philpott and Armbrecht (2006) discuss the costs and benefits of promoting ants in agroecosystems from their functional role as predators and the known impacts of intensive agriculture practices on their diversity. No direct or indirect quantification of service delivery is either made or inferred.</td>
</tr>
<tr>
<td>Proxies</td>
<td>Use of biodiversity aspects—such as species richness or abundance—as proxies for ES provision, instead of quantifying the relationship between ES and insects.</td>
<td>Frank et al. (2008) assess the potential benefits of promoting certain native plants in croplands, assuming that the richness and abundance of natural enemies inhabiting these plants are a good proxy for their effectiveness for biological control.</td>
</tr>
<tr>
<td>Direct quantification</td>
<td>Direct quantification in the field of the ES provided by insects, without following any experimental design.</td>
<td>Thies et al. (2005) quantify the increase in aphid mortality by parasitoids in different landscape conditions, as a direct measure of his latter group on biological control.</td>
</tr>
<tr>
<td>Experiments</td>
<td>Quantification of the ES through laboratory or field experiments, with one or more environmental and/or biotic factors being controlled for.</td>
<td>Brittain et al. (2010) measure pollinator abundance and richness, flower visitation rates, pollination of experimental potted plants and seed production to quantify pollination in their analysis of the benefits of organic farming in different landscape contexts.</td>
</tr>
