Abstract

The diarylethene moiety is one of the most extensively used switches in the field of molecular electronics. Here we report on spectroscopic and quantum chemical studies of two diarylethene-based compounds with a non- C_3 -symmetric triethynyl terthiophene core symmetrically substituted with RuCp*(dppe) or trimethylsilyl termini. The ethynyl linkers are strong IR markers that we use in time-resolved vibrational spectroscopic studies to get insight into the character and dynamics of the electronically excited states of these compounds on the ps-ns time scale. In combination with electronic transient absorption studies and DFT calculations our studies show that the

3 conjugation of the non- C_3 -symmetric triethynyl terthiophene system in the excited
4 state strongly affects one of the thiophene rings involved in the ring closure. As a
5 result, cyclisation of the otherwise photochromic 3,3''-dimethyl-2,2':3',2''-terthiophene
6 core is inhibited. Instead, the photoexcited compounds undergo intersystem crossing
7 to a long-lived triplet excited state from which they convert back to the ground state.

15 Introduction

16
17
18 The top-down approach in lithography is rapidly reaching its theoretical limit, with the
19 last decade showing solid-state devices approaching the nano-scale.¹⁻⁵ The bottom-up ap-
20 proach, that is fabricating molecular devices capable of imitating macroscopic machinery,
21 is therefore increasingly attracting attention.⁶⁻⁹ In this bottom-up approach the reversible
22 photoisomerization reaction of diarylethene that has been studied extensively since the first
23 report in 1988¹⁰ is an often employed component for constructing novel molecular electronic
24 devices.¹¹⁻¹³ Diarylethene-based compounds have proven to be thermally irreversible, resis-
25 tant to fatigue, and to exhibit a highly efficient ring closure, making them prime candidates
26 for electronic switches.^{4,11,14,15}

36 The compounds of interest in this work, **1a** and **1b** shown in **Figure 1**, have diarylethene
37 cores constructed using a thiophene bridging unit. The thienyl groups are attached at the 2-
38 and 3-positions of the central bridging thiophene ring, **Figure 2**. Unlike more common bridg-
39 ing units, such as octafluorocyclopentene, diarylmaleic anhydride or diarylmaleimide,^{11,16,17}
40 thiophene has the potential to reduce expenses, due to a more efficient synthesis using less
41 volatile starting materials, which enables the upscale of production.¹⁸ The terthiophene
42 core explored in this research (**Figure 2**) has demonstrated photocyclisation,^{18,19} thereby
43 closely following the observation of ring closure in terthiophenes in general¹² with and with-
44 out substituents on the terthiophene core.²⁰ However, it should be noted that the literature
45 regularly reports a more commonly used diarylethene structure (1,2-bis(2-methylthiophen-
46 3-yl)ethene) where the positions of the sulphurs differ to the ones presented here. This study

utilises inverse diarylethenes which have shown ring closure.²¹ One of the main reasons for diarylethenes failing to cyclise is a result of the parallel conformation, in which the central methyl groups point in the same direction.^{11,22} The addition of bulky groups on the other hand promote the reactive anti-parallel form.²³

1
2
3 The motivation for investigating **1a** and **1b** is an extension of work on dinuclear organometallic-
4 substituted diarylethenes^{11,17,23} in which the degree of sophistication of diarylethenes was
5 increased by creating a multifunctional (photo and redox) switch. Ethynyl-bridged metallic
6 complexes have been extensively studied,^{4,24-27} and found to exhibit electronic properties
7 that are influenced by the metal and the carbon-rich bridges.²⁶ Dinuclear organometallic
8 compounds have been constructed with central diarylethene and ethynyl-bridged metallic
9 termini.²⁸ Importantly, these compounds retain their photochromic properties^{17,23} but can
10 also be switched electrochemically.^{16,17} From this research further insight was obtained on
11 the electronic communication between the termini in both the open and closed states.

19
20
21 The alignment of a thiophene bridge to diarylethenes allowed for a terthiophene system
22 to be investigated. The electronic and bonding properties of **1a** and **1b** have been pre-
23 viously elucidated by anodic spectro-electrochemistry.²⁹ Compound **1a** did not show any
24 anodic steps within the accessible potential window, nor was there any evidence for photo-
25 cyclisation. Replacing the TMS groups in **1a** with the RuCp*(dppe) termini in **1b** results in
26 the appearance of three consecutive oxidation steps.²⁹ In the open form of **1b** it was found
27 that the lateral electrophores do not communicate directly and oxidise independently. In
28 view of previous results²³ that showed that the introduction of ruthenium to the system en-
29 hances photocyclisation of diarylethene from triplet excited states, ring closure appeared to
30 be an attractive strategy to increase the electronic communication between the electrophores.
31 However, unlike the dinuclear analogs^{17,28} UV/Vis spectro-electrochemistry of **1b** showed no
32 evidence of cyclisation in any of the three anodic steps.²⁹ Since the 3,3''-dimethyl-2,2':3',2''-
33 terthiophene core by itself does show photoreactivity,^{18,19} it is key to understand how the
34 highly conjugated ethynyl linkers in these systems inhibit photocyclisation, as this will pave
35 the way for developing photoreactive trinuclear systems with a variable degree of electronic
36 communication between the remote termini.

tural changes in real time have commonly employed UV/Vis transient absorption spectroscopy.^{32–37} Vibrational spectroscopy has been taken advantage of by using picosecond time-resolved Stokes and anti-Stokes Raman spectroscopy³⁸ to follow the cyclisation mechanism with an experimental temporal resolution of ~ 4 ps. However, femtosecond time-resolved UV/Vis-IR studies offer a significantly more detailed view on such dynamics⁷ but as yet are absent. The ethynyl groups have demonstrated to be infrared markers that sensitively respond to changes in the oxidation state.^{24,29} As will be shown here, time-resolved infrared spectroscopic (TR-IR) studies that target these modes are therefore an ideal means to monitor the changes that occur in the electronic structure upon excitation of the trinuclear non- C_3 -symmetric terthiophene compounds of interest. This, in turn, will allow us to determine the underlying reasons for the photostability of these compounds and suggest modifications to enable cyclisation.

Experimental Methods

Synthesis and Sample Preparation

Compounds **1a** and **1b** were synthesised as reported in the literature.²⁹ Initially, dichloromethane (DCM) dried over 4 Å molecular sieves was used as a solvent. After the discovery of photo-oxidation of **1b** in DCM (see **Section S1** in SI) anhydrous ($\geq 99.9\%$), inhibitor-free tetrahy-

1
2
3 drofuran (THF) purchased from Sigma Aldrich was used as well as an alternative solvent. In
4 our nanosecond UV/Vis transient absorption and time-resolved IR absorption experiments
5 the solution was pumped through a cell so that fresh sample was probed with each laser shot.
6 This was not possible for the femtosecond UV/Vis transient absorption experiments, but in
7 these experiments steady-state absorption spectra taken before and after the experiments
8 showed no degradation of **1a** in both solvents or of **1b** in THF. The sample concentrations
9 were adjusted to obtain absorbances of 0.8 - 1 at the pump wavelength (400 nm). All samples
10 were prepared under an inert atmosphere of dry nitrogen. The samples were bubbled with
11 dry argon prior to the measurements. Steady-state UV/Vis and IR absorption spectra of **1a**
12 and **1b** are given in the SI, **Section S2**.

25 Femtosecond Transient Spectroscopy

26
27 Time-resolved infrared spectroscopy was performed using commercially available Ti:sapphire
28 lasers (Spectra-Physics Hurricane, 600 μJ , ~ 100 fs FWHM and Coherent, 2 mJ, ~ 50
29 fs FWHM). With the amplified output from these lasers and an optical setup described
30 elsewhere,³⁹ mid-IR pulses with a duration of 200 fs, a bandwidth of 150 cm^{-1} and an
31 energy of 1 - 3 μJ were produced. UV-pump pulses at 400 nm with energies of 4 μJ were
32 generated by doubling the amplified 800 nm output with a type II BBO crystal, and were
33 delayed by mechanically adjusting the beam path. The UV pump was focused and spatially
34 overlapped with the mid-IR probe, and a temporal resolution of ~ 200 fs (FWHM) was
35 determined as described previously.⁷ The signals were recorded using an electronically gated
36 amplifier, an Oriel M260i spectrometer and a 32 pixel MCT detector. The samples, in a
37 flow cell equipped with CaF_2 windows spaced by 1 mm, were placed in the mid-IR focus and
38 pumped through the cell to ensure a fresh sample being measured with each laser shot.

2
3 The fundamental light used for the white-light generation was passed twice over a delay
4 stage, providing up to 3.6 ns time delay. The sample cell was a 1 mm quartz cuvette. The
5 pump light (400 nm) was created as mentioned above and ran at 500 Hz, using a mechanical
6 chopper to produce a non-pumped signal acting as a reference measurement. The spectra
7 were measured using a spectrograph (Shamrock 193i with a 150 lines/mm grating) and a
8 single diode-array (Hamamatsu NMOS S3901-512Q) detector. The readout was done using
9 fast electronics (TEC5).

19 Nanosecond Transient Spectroscopy

20
21 Nanosecond transient absorption was measured using an in-house assembled setup described
22 elsewhere.⁴⁰ A tunable Nd:YAG-laser system (NT342B, Ekspla) produced the 400-nm pump
23 pulse of 1 mJ that passed through the sample orthogonal to the probe light. The white-light
24 source was a high-stability short-arc xenon flash lamp (FX-1160, Excelitas Technologies)
25 with a modified PS302 controller (EG&G). Transient absorption spectra were measured on
26 a gated intensified CCD camera (PI-MAX3, Princeton Instruments) using a 10 ns gate. The
27 samples were continuously pumped through a 1 cm quartz cuvette, so that only fresh samples
28 were measured.

Results and Discussion

To obtain insight into the optically excited state of **1a** and its dynamics, we first performed femto- and nanosecond vis-pump/vis-probe experiments in THF (**Figures 3** and **4**, respectively). Femto- and nanosecond transient spectra were also recorded in DCM (SI, **Section S3 (Figures S7 and S8)**), with no appreciable difference as compared to THF. In both solvents, **1a** was optically excited with 400 nm photons. TD-DFT calculations of the vertical transitions from the ground state show that the transition with the lowest excitation energy occurs at 3.11 eV (398 nm) with an oscillator strength of $f=0.7217$, and that it is predominantly described by the HOMO \rightarrow LUMO (SI, **Section S4 (Figure S10)**) excitation. The calculated electronic absorption spectrum (SI, **Section S4 (Figure S13)**) is in good agreement with steady-state UV-Vis spectra of **1a**, (SI, **Section S2 (Figure S5)**). In the transient spectra (**Figure 3**) of **1a** we can distinguish three spectral features. Initially, within a few ps, a broad feature is seen across the entire spectral window with two distinctive maxima at 550 and 705 nm. From this state it converts to a second state that is blue-shifted by ca. 25 nm (evident from the decay-associated spectra (DAS) shown in the SI, **Section S3 (Figure S9)**) but maintains similar spectral features, hinting the initial state to be a hot singlet-excited state. Subsequently a third feature showing a strong absorption at roughly 400 - 550 nm becomes apparent. This third transient species does not decay within the 4 ns delay range accessible in our femtosecond setup. The transient data matrix for the femtosecond time domain was globally fitted using an open-source program Gloteran,⁴⁹ assuming a sum of exponential time profiles and a sequential model (1):

In this model vertical excitation ($h\nu$) populates a hot singlet state S^* which is converted into a relaxed singlet state S with a time constant of $\tau_1 = 7 \pm 2$ ps. The transition from the relaxed singlet state to the triplet state T (as follows from the TR-IR data and TD-DFT

Figure 3: Femtosecond UV/Vis transient absorption spectra of **1a** in THF excited at 400 nm. The DAS is shown in the SI, **Figure S9**.

Figure 4: Nanosecond UV/Vis transient absorption spectra of **1a** in THF excited at 400 nm.

calculations discussed below) takes $\tau_2 = 119 \pm 2$ ps. The DAS, from the electronic differential absorption measurements, of the S^* , S and T states of **1a** are given in the SI (**Section S3** (**Figure S9**)). In order to further monitor the decay of these electronically excited molecules, nanosecond transient absorption spectra were recorded for **1a** (**Figure 4**) excited at 400 nm. Singular Value Decomposition (SVD)⁵⁰ of the nanosecond transient spectra shows the decay of a single transient species. We have therefore, using model (2), performed a global analysis of the nanosecond transient data matrix assuming a sum of exponential time profiles and T-T annihilation (described in detail in **Section S5** in the SI):

From these fits we find a lifetime of the triplet state of $\tau_3 = 22.7 \pm 0.5 \mu s$, fits are shown in **Figure 5**. The spectral features in the visible region in the nanosecond time domain show no evidence of other transient species, and the long lifetime provides further evidence for triplet-state formation. For aerated solutions the rate of the $T \rightarrow GS$ conversion increased for **1a** ($\tau_{3,air} = 410 \pm 2$ ns), again confirming that T is a triplet state.

Complementary TR-IR experiments were performed to obtain a better insight into the

Figure 5: Decay of the transient absorption signal of **1a** (**1b**) at 580 (650) nm in the nanosecond time domain. Spectral absorbances have been normalised.

electronic structure of each excited state and to determine what inhibits photocyclisation of **1a**. The evolution of the TR-IR spectra of **1a** after excitation at 400 nm is shown in **Figure 6**. Adopting a target model (1), global fits of the TR-IR spectra lead to time constants of $\tau_1 = 3.0 \pm 1$ ps and $\tau_2 = 114 \pm 2$ ps for **1a**, and the TR-IR decay-associated spectra (TR-IR DAS) that are shown in (**Figure 6**). Comparison of the TR-IR DAS of the initial species (S^*) with that of the second species (S) reveals a narrowing of the induced absorption band and shift to a slightly higher energy of ~ 3 cm^{-1} , in line with the conclusion that vibrational cooling of the hot excited singlet state occurs. The femtosecond TR-IR measurements thus confirm that the initial S^* state is a hot electronically excited state (note that the TA and TR-IR transients have the same rates of decay). Importantly, neither type of experiments indicates the presence of a ring-closed species. Various parameters such as solvent polarity and excitation wavelength have been changed to see whether under different conditions cyclisation might occur, but in all cases no indication was found for cyclisation or even a markedly different transient behaviour.

Figure 6: Left: Femtosecond TR-IR spectra of **1a** in DCM and excited at 400 nm. Right: TR-IR decay-associated spectra (DAS) derived from the TR-IR spectra of **1a**.

Figure 7 shows DFT and TD-DFT predicted IR absorption spectra in the ethynyl stretching region for the ground and excited states of **1a**, with frequencies scaled by 0.95 (which closely follows what is reported in the literature⁵¹) and presented in **Table 1**. Overall good agreement is observed between the experimental and theoretical spectra. Experimentally a ground-state (GS) bleach is observed at 2135 cm^{-1} . The calculations show that this band actually consists of three unresolved bands from the three different stretching modes of the ethynyl linkers. The calculated highest-frequency mode at 2136 cm^{-1} involves mainly the central thiophene ethynyl, labelled **e2** in **Figure 1**. The lower-frequency components at 2132 cm^{-1} and 2131 cm^{-1} are assigned to the symmetric and antisymmetric stretching modes of the ethynyl linkers at the lateral thiophenes (**e1** and **e3** in **Figure 1**). From the experimentally observed and theoretically predicted small frequency differences one can thus conclude that in the ground state all three linkers are more or less equivalent, and that a complete delocalisation of the vibrational excitation occurs over the terthiophene backbone.

This is in marked contrast with the initial singlet excited state (S in **Figures 6** and **7**), for which there is a lowering of energy of the bands. This is observed in both the experimental and theoretical spectra. The lower energy indicates a weakening of the ethynyl bonds and is in line with what one would expect, but much more surprising is the observation that there

Figure 7: Theoretically predicted IR absorption spectra of the ground state, the lowest excited singlet state and the lowest excited triplet state of the open form of **1a** as well as of the ground state of its cyclised form. All calculated modes have been broadened to give a FWHM of 4 cm^{-1} .

are three very distinct bands, since this can only be explained by assuming that the electronic excitation is not equally delocalised over the three linkers. Our calculations show that the main contributions to the experimentally observed absorption bands at 2097, 2075 and 2069 cm^{-1} come from **e3**, **e2** and **e1**, respectively (**Figure 1**). These frequency differences nicely follow the changes in bonding character that arise from the HOMO \rightarrow LUMO transition (SI, **Section S4 (Figure S10)**), which takes the **e1** C \equiv C from a bonding state in the HOMO to an antibonding state in the the LUMO. For the **e2** C \equiv C the antibonding character is less pronounced than for **e1**, and even less for the **e3** C \equiv C for which the LUMO is almost non-bonding. The asymmetry of the non- C_3 -symmetric terthiophene core thus has dramatic consequences for the character of the excitation, for which we can now conclude is strongly localised on the **e1** thiophene arm, to a lesser extent on the **e2** arm, and leaves the **e3** arm practically unaffected.

TD-DFT calculations have also been performed for the lowest excited triplet state (**Figure**

7). The agreement between theory and experiment is in this case considerably less than observed above for the lowest excited singlet state. Interestingly, we find that calculations at the unrestricted DFT (U-DFT) level lead to a much better agreement (see **Figure 7**) indicating that a variational treatment apparently is better able to recover the character of this state than the perturbation approach used in TD-DFT (this has been found to be the case for similar systems in the literature⁵²⁻⁵⁴). Inspection of the modes calculated at the U-DFT level shows that the mode calculated at 2014 cm^{-1} is associated with the asymmetric stretching mode of **e1** and **e2** with the major contribution coming from **e1**. The corresponding symmetric stretching mode with **e2** being most involved is found at 2048 cm^{-1} , while the **e3** stretching is solely responsible for the IR absorption at 2119 cm^{-1} . The latter mode is not directly apparent in the experimental TRIR spectra because of its overlap with the GS bleach, but on closer inspection can be found by the shoulder that is visible at about 2110 cm^{-1} and the partial recovery of the GS bleach at a similar rate as the population of the triplet state.

Previously we have concluded that in the lowest excited singlet state the excitation is strongly localised on two of the arms. Comparison of the IR absorption spectra of the lowest excited singlet and triplet states shows that in the lowest triplet state such a localisation is even more pronounced. The frequency of the **e3** $\text{C}\equiv\text{C}$ stretch mode increases with energy with respect to that of the lowest excited singlet state and almost the same as in the ground state while at the same time the absorption bands associated with the **e1** and **e2** $\text{C}\equiv\text{C}$ stretch modes undergo a decrease in energy.

Figure 7 and **Table 1** also present DFT-calculated IR absorption bands for the ground state of the hypothetical photo-cyclised form of **1a**. Here we find symmetric and antisymmetric combinations of **e1** and **e3** at 2141 and 2142 cm^{-1} , respectively, while the stretch mode of the central **e2** ethynyl group is calculated at 2129 cm^{-1} . Despite the lack of experimental evidence for photo-cyclisation, the DFT calculations do not exclude its occurrence. Relative to the GS the S is 61.3 kcal mol^{-1} higher in energy. The T(U) is calculated to

be 42.8 kcal mol⁻¹ higher than the GS while the T(TD) predicts it to be 36.5 kcal mol⁻¹ higher than the GS. The energy of **1a** is about 35 kcal mol⁻¹ higher for the cyclised complex compared to the parent open-triangle form in the GS. Hence, cyclisation from the S state or the triplet state (either the U or TD) is energetically feasible; albeit the TD calculated triplet state energy is very close to that of the cyclised compound. Therefore it is likely there is a high activation barrier in all the excited states that cannot be overcome.

Table 1: Calculated frequencies of **1a** (scaled by 0.95) and experimentally observed frequencies of **1a** and **1b**.

Bond	Calculated Frequencies of 1a (cm ⁻¹)

e2 (1b)	-	1980	1980	1992 ²⁹	
e3 (1b)	-	2020	2030	2049 ²⁹	

Another possible reason that photoexcitation does not lead to cyclisation could be that the methyl groups do not have the appropriate orientation for ring closure to occur. Previous work^{11,13} has shown that for the parallel conformer cyclisation is inhibited. Although DFT calculations do not show an appreciable energy difference between the two forms, the anti-parallel form being a mere 0.1 kcal mol⁻¹ lower in energy, NOESY measurements on **1a** (SI, **Section S6 (Figures S15 and S16)**) provide no evidence for the presence of the parallel conformer in the ground state. Upon excitation the anti-parallel form might convert to the parallel conformer by rotation about one of the bridging bonds, viz. C₁₆ – C₂₆ or C₂₅ – C₃₆

1
2
3 (Figure 1). SVD⁵⁰ in the nanosecond time domain reveals only a single transient species,
4 while the picosecond dynamics can be well explained by vibrational cooling and intersystem
5 crossing to the triplet manifold. The literature, backed up by our NMR measurements (SI,
6 Section S6 (Figure S17)), also rules out *E/Z*-isomerization as a possible reason for absence
7 of cyclisation, as the bridging thiophene unit prevents the formation of the *E*-form.¹³
8
9

10
11 The TR-IR measurements backed up by the TD-DFT calculations show that the HOMO
12 has equal contributions from the three arms but that the LUMO resides heavily on the
13 left side of **1a**. These orbitals closely resemble the analogous orbitals found in previous
14 work²⁹ on **1b**. In line with our conclusions regarding the influence of the asymmetry on the
15 electronic properties, calculations on **1b**⁺ show that in the oxidised form the spin density
16 asymmetrically distributed with the largest contributions from the thiophenes involved in
17 the **e1** and **e2** arms. The asymmetry by itself cannot be the only reason why **1a** does
18 not undergo ring closure, since from previous studies it is known that non-*C*₃-symmetric
19 terthiophene cores^{18,19} can cyclise. In the following we will argue that the attachment of the
20 ethynyl-based substituents onto the non-*C*₃-symmetric terthiophene core lead to changes in
21 the conjugation which in turn are expected to have a major impact on the photocyclisation
22 pathway.

37 Our TR-IR studies show that electronic excitation has a large influence on the bonding
38 properties of the **e1** ethynyl linker: instead of the triple bond character it has in the ground
39 state, bonding becomes reduced. The same is true for the **e2** ethynyl linker albeit to a
40 lesser extent. In terms of valence bond structures this implies that the contribution of the
41 structure depicted in **Figure 8** to the electronic wavefunction is increased considerably in the
42 electronically excited states. Our observation that in the photoexcited triplet state bonding
43 characters are more reduced than in the photoexcited singlet state demonstrates that in the
44 triplet state this mesomeric structure has an even larger contribution than in the singlet
45 state. This increased contribution has a major impact on the conjugation in both states as
46 becomes clear from the bond lengths reported in the **Table S1, Section S4** of the SI. The

Figure 8: Valence bond structure of **1a** that gains importance in the singlet and triplet excited states. Charge size and colour annotated on the arms indicate the degree of charge separation, the **e1** arm thus having a larger degree of charge separation than **e2**.

calculations show that the **e1** and **e2** ethynyl bonds $C_{11} - C_{12}$ and $C_{21} - C_{22}$ (numbered in **Figure 1**) lengthen in both S and T compared to GS while for the **e3** ethynyl bond $C_{31} - C_{32}$ the change in bond length is much smaller. At the same time, they show for the thiophene ring attached to **e1** a sizable shortening of the $C_{14} - C_{15}$ bond (a change in the electron density of this bond, from the HOMO to the LUMO, can be clearly seen in the SI **Section S4 (Figure S11)**) and a lengthening of $C_{13} - C_{14}$ and $C_{15} - C_{16}$ bonds, giving rise to a quasi inversion of single and double bond character upon excitation. Finally, also the $C_{16} - C_{26}$ bond connecting the **e1** and **e2** thiophene arms changes from a single into a double bond. Analogous but smaller changes are observed for the **e2** arm while the **e3** arm is hardly affected. Cyclisation is clearly a highly unfavourable process for the mesomeric structure depicted in **Figure 8**. In order to cyclise the $C_{13} - C_{14}$ bond, which has been shown to have double bond like characteristics in the excited state (SI, **Section S4 (Figure S11)**), would have to become unsaturated, having a knock on effect on the conjugation throughout the whole molecule. The increased contribution in the electronically excited states thus provides a logical explanation for the absence of photocyclisation in both the singlet and triplet states.

The insight that we have now acquired on the electronic structure of **1a** and how this

1
2
3 structure changes upon photoexcitation provides an excellent starting point for assessing
4 the influence of the ruthenium termini in **1b**. Importantly, **1b** also enables us to compare
5 the properties of the photo-excited compound with those of the electrochemically oxidised
6 one which was not possible for **1a** as electrochemical studies of the latter have not been
7 reported yet. **Figure 9** displays nanosecond UV/Vis transient absorption spectra of **1b**.
8 Nanosecond UV/Vis transient absorption experiments show that photoexcitation of **1b** in
9 THF eventually populates the triplet state T (**Figure 9**). As a result of the ruthenium
10 termini absorption from T now occurs at ca. 650 nm and is thus strongly red-shifted from
11 the ca. 480 nm absorption observed for **1a**. Global analysis of these data using model S1 (SI,
12 **Section S5**) that assumes a sum of exponential time profiles and triplet-triplet annihilation
13 lead to a time constant $\tau_3 = 8.3 \pm 0.5 \mu\text{s}$ for the T \rightarrow GS decay which is a factor three faster
14 than observed for **1a**, fits are shown in **Figure 5**. This increase in decay rate is not surprising
15 in view of the increased spin-orbit coupling in **1b** due to the Ru atoms. Femtosecond UV/Vis
16 transient absorption spectra of **1b** (SI, **Section S7 (Figure S18)**) show that the triplet
17 state is populated within the first 20 ps but do not provide a clear view on the early-time
18 dynamics.

Previously, it has been shown that attachment of the ethynyl-metal based substituents
onto a symmetric terthiophene core does not impede cyclisation.^{17,23} In the present exper-
iments, in contrast, we do not observe any evidence for cyclisation. In fact, from the full
recovery of the GS bleach in **Figure 9** it can be concluded that in THF **1b** completely
reverts back to the GS.

TR-IR spectra of **1b** are shown in **Figure 10**. Global analysis of these spectra gives
rise to two species with DAS that are displayed in **Figure 10**. The final species can clearly
be associated with T which is populated with a time constant of $\tau_2 = 5 \pm 2$ ps. This is
considerably faster than what is observed for **1a** but entirely in line with the strong spin-
orbit coupling due to the presence of the Ru atoms that was previously concluded to be
responsible for the increased decay rate of the triplet to the ground state. The assignment

Figure 9: Nanosecond UV/Vis transient absorption spectra of **1b** in THF excited at 400 nm.

of the first species, on the other hand, is not directly clear. It could be associated with the initially excited singlet state, but this would imply that the excited singlet and triplet states have very similar ethynyl stretch frequencies which—in view of our observations for **1a** where distinct IR absorption spectra were observed for both states—would not directly be expected. Alternatively, the narrowing of the bands in the DAS of the second species as compared to those in the first species and the decay rate of the first species would be in line with a vibrational cooling process occurring in the triplet manifold. In that case intersystem crossing would be faster than the ~ 1 ps time resolution of our TR-IR experiments.

Comparison of the ethynyl vibrational characteristics of **1a** and **1b** shows that in the ground state of **1b** frequencies are reduced by about 100 cm^{-1} , indicating delocalisation of the conjugation over the Ru termini, this is backed up by the HOMO plots of **1b** in the SI Section 4 (Figure S12). However, in the triplet state the ethynyl modes undergo the same asymmetric frequency shifts in **1b** as in **1a** as can be concluded from Table 1. We thus conclude that in both compounds electronic excitation leads to very similar changes in the

Figure 10: Left: Femtosecond TR-IR spectra of **1b** in THF excited at 400 nm. Right: TR-IR decay-associated spectra (DAS) of **1b**.

electronic structure, and in particular to an increase of the contribution of the mesomeric structure shown in **Figure 8**. In **Section S4 (Figure S12)** of the SI the LUMO + 1 of **1b** is shown. The calculations of the 10 lowest energy vertical transitions are shown in the SI **Section S4 (Figure S14)** which show one dominant transition associated with the HOMO \rightarrow LUMO + 1 transition. The comparison of the LUMO of **1a** and the LUMO + 1 of **1b** confirms the similarities between the excited states, especially when comparing the LUMO/LUMO + 1 on the $C_{14} - C_{15}$ bond of the two compounds. It would therefore appear that modifying the arms with the Ru termini —aiming thereby to change the asymmetry in the character of the electronically excited states as well— does not change the conjugation to such an extent that cyclisation becomes possible.

Interestingly, we find that the changes in the ethynyl frequencies in the triplet state of **1b** closely follow the changes when **1b** is oxidised (**Table 1**).²⁹ The asymmetry in the electronic wavefunction of **1b**⁺ is further supported by the spin density distribution which is found to reside heavily on the lateral side of **1b**⁺ between **e1** and **e2**. Moreover, the electronic absorption spectrum from the triplet state of **1b** and the ground state of **1b**⁺ show similar features, both having strong absorption bands with maxima at ca. 730 nm for **1b**⁺ (SI, **Section S1 (Figure S3)**) and ca. 680 nm for the T state (**Figure 9**). These

1
2
3 spectroscopic markers thus indicate that **1b** in its lowest excited triplet state is similar to
4 the ground state of the one-electron oxidised form. This suggests that the photoinduced
5 promotion of an electron from the HOMO to the antibonding LUMO (**1a**)/ LUMO + 1 (**1b**)
6 and the complete electrochemical removal of an electron from the HOMO both result in a
7 similar weakening of the **e1** and **e2** ethynyl characteristics and modified conjugation in the
8 terthiophene core.

17 Conclusions

18
19
20 To summarise, we have investigated two open-triangle triethynyl terthiophene compounds,
21 **1a** and **1b**, that show a surprising photostability instead of switchable photocyclisation.
22 Visible transient spectroscopy has unveiled the decay pathways of both compounds that
23 populate the triplet state manifold. Using the ethynyl groups as sensitive IR markers for
24 the electronic structure of these compounds in ground and electronically excited states, we
25 have shown that in both compounds electronic excitation induces an electronic asymmetry
26 in the terthiophene core. The concurrent reduction of electronic delocalization has far-
27 reaching consequences, as it increases the importance of mesomeric structures that do not
28 favor cyclization —as is indeed observed. Although the addition of the Ru termini extends
29 delocalization of the electronic wavefunction in the ground state, it does not modify the
30 electronic structure of the electronically excited states as to enable cyclization.

43 The present study has revealed what prevents photocyclization in these asymmetric ter-
44 thiophene compounds. It thereby provides a solid starting point for designing novel com-
45 pounds in which asymmetry could be compatible with gating electron and energy transfer
46 using photocyclization and electrochemistry. Such studies are presently underway.

Diarylethene is one of the most commonly used photoswitches in the molecular-electronics field. Interestingly, two new diarylethene-based compounds (incorporated into a non-C3-symmetric terthiophene core) show unexpectedly great resistance to photocyclisation. Time-resolved vibrational spectroscopy reveals that photo-switching is prevented by the asymmetric character of the excited state. These results provide a solid starting point for designing novel compounds in which asymmetry could be compatible with gating electron and energy transfer.
