24 Abstract

In this study, the impact of different land initial conditions on the simulation of thunderstorms 25 and monsoon depressions is investigated using the Weather Research and Forecasting (WRF) 26 model. A control run (CNTL) and a simulation with an improved land state (soil moisture and 27 temperature) using the High Resolution Land Data Assimilation System (HRLDAS, 28 29 experiment name: EHRLDAS) are compared for three different rainfall cases in order to examine the robustness of the assimilation system. The study comprises two thunderstorm 30 31 cases (one in the pre-monsoon and one during the monsoon) and one monsoon depression case 32 that occurred during the Interaction of Convective Organisation, Atmosphere, Surface and Sea (INCOMPASS) field campaign of the 2016 Indian monsoon. EHRLDAS is shown to yield 33 improvements in the representation of location-specific rainfall, particularly over land. Further, 34 35 it is found that surface fluxes as well as convective indices are better captured for the premonsoon thunderstorm case in EHRLDAS. By analysing components of the vorticity tendency 36 equation, it is found that the vertical advection term is the major contributor towards the 37 positive vorticity tendency in EHRLDAS compared to CNTL, hence improving localised 38 convection and consequently facilitating rainfall. Significant improvements in the simulation 39 40 of the pre-monsoon thunderstorm are noted, as seen using Automatic Weather Station (AWS) 41 validation, whereas improvements in the monsoon depression are minimal. Further, it is found 42 that vertical advection (moisture flux convergence) is the major driver modulating the 43 convective circulation in localised thunderstorm (monsoon depression) cases and these dynamics are better represented by EHRLDAS compared to CNTL. These findings underline 44 the importance of accurate and high resolution land-state conditions in model initial conditions 45 46 for forecasting severe weather systems, particularly the simulation of localised thunderstorms over India. 47

49 **1. Introduction**

The eastern part of India is vulnerable to the landfall of intense tropical storms and 50 thunderstorms, which affect lives, livelihood and property in the region. The state of Odisha, 51 located on the east coast of India is highly susceptible to natural disasters arising from 52 thunderstorms (lighting), intense rainfall events from synoptic-scale monsoon low pressure 53 54 systems (or monsoon depressions), and cyclones (Das, 2017; Mohapatra & Mohanty, 2005; Dube & Rao, 2005). The large number of deaths in recent years (the second highest in the 55 country) has led to Odisha being named the "lightning graveyard" of the country. However, 56 57 only a limited range of studies has been targeted at this region to address the problem. Furthermore, the genesis of localised convection and associated rainfall have several 58 limitations in Weather Research and Forecasting (WRF) (Alvarez et al., 2018). The analysis 59 60 shows that the underestimation by the model is probably due to inability of model to generate convection, apparently related to processes of larger scale and limitations on describing 61 mesoscale processes that leads to vertical movements capable of producing extreme rainfall. 62 Apart from many other factors, accurate information of the initial state of land and atmospheric 63 conditions plays a major role in rainfall prediction at the numerical weather prediction (NWP) 64 65 scale. Numerous studies (Osuri et al., 2017; Pielke et al., 2007; Rajesh et al., 2016) have shown 66 that improvement in short-range prediction of boundary layer development, cloud fields and 67 precipitation may rely on detailed representation of land surface physics and accurate 68 initialization of the land state (i.e. soil moisture, soil temperature, vegetation and land use/land cover). The role of patterns of soil moisture and soil temperature in deep convective 69 70 development and thermodynamic structure of the atmosphere has also been recognised (Taylor 71 et al., 2012), including specifically for northern India (Barton et al., 2019). Baisya (2017) demonstrated that there is strong influence of land surface conditions on precipitation 72 characteristics of monsoon depressions in term of spatial distribution and intensity of rainfall. 73

Further, they have demonstrated that initial soil moisture condition and soil moisture
availability have strong influence on the rainfall spatial distribution and intensity respectively,
over the east coast of India.

77 One of the key roles of soil moisture is to partition the available surface energy into latent and sensible heat fluxes, among which latent heat flux is directly proportional to 78 evapotranspiration, since it is the sum of transpiration, soil evaporation and canopy evaporation 79 (Lawrence et al. 2007; Yuan et al. 2017). These three components of evapotranspiration are 80 calculated within the land surface scheme, thus stressing the role of land-atmosphere 81 82 interaction in numerical weather prediction models. Taylor et al., 2012 suggested that semiarid regions have more relation between soil moisture and associated precipitation and this 83 mechanism is modulated by any changes in surface fluxes of moisture and heat (latent and 84 85 sensible). Past studies have suggested that localised Convective Available Potential Energy (CAPE), high surface temperature and elevated moisture content (upper troposphere) are 86 important ingredients to fuel to the eventual development of deep cumulus convective clouds 87 88 and rainfall (Murugavel et al., 2014; Price et al., 2010).

Monsoon depressions are synoptic-scale systems which form over the Bay of Bengal and move in a westward/north-westward direction and often make their entrance to central India through Odisha, thereby causing heavy rainfall there. It is found that moisture flux convergence is the main source of moisture for such systems, while local evaporation is of lesser importance (Rajesh et al., 2017; Hunt & Turner, 2017). Rajesh et al., (2017) have already demonstrated improvements in the prediction of rainfall and other convective parameters for monsoon depressions using high resolution land data assimilation techniques.

The major problem limiting the accurate initiation of a model is the scarcity of high spatial resolution observations of the land surface over the model domain. This scarcity of high resolution land surface observations can be overcome by combining satellite observations with

99 high resolution land-surface models. In this context, High Resolution Land Data Assimilation System (HRLDAS) is a land data assimilation system based on the Noah Land Surface Model, 100 and is a modelling interface in conjunction with WRF. Its dynamical framework calculates 101 temporal changes in surface energy fluxes such as sensible, latent, ground heat fluxes, net 102 radiation, soil moisture and temperature, soil water content and surface runoff etc., in offline 103 mode (Rajesh et al., 2016 & 2017). Various assimilation studies have proved that imposing 104 105 different soil moisture conditions can modulate the surface temperature forecast (due to localised interactions between the land surface and overlying atmosphere), but among non-106 107 local factors, the horizontal transport of moisture is the dominant parameter impacting the model's predicted rainfall. Eltahir (1998) demonstrated that wet soil moisture would enhance 108 109 the moist static energy in elevated boundary layer and would be associated with more rainfall. 110 Previous studies have suggested that co-varying patterns of temperature and rainfall indicate strong coupling of the land and atmosphere and implying the need to improve the initial land 111 state to simulate heavy rainfall events (Koster et al., 2005). In addition, assimilation of high 112 resolution satellite data has also been shown to have a positive influence on the dynamic and 113 thermodynamic features of monsoon depressions along with the spatial distribution of the 114 simulated precipitation over India (Kumar et al., 2014). Despite the positive impacts of various 115 data assimilation methods on the prediction skill of forecast rainfall for short-range forecasts 116 (Bohra et al., 2006; Routray et al., 2008), there is a scarcity of this kind of study examining the 117 118 impact of land surface assimilation on the prediction skill of NWP models for India, especially for improving the forecast of localised heavy rainfall events. 119

Thus, this manuscript is targeted at addressing this problem particularly over the state of Odisha (east coast India) with the aim to evaluate the influence of improved land surface assimilation on the prediction skill of localised rainfall and to understand associated feedback mechanisms. The method followed is to test the implementation of the HRLDAS scheme in the Weather Research Forecast (WRF) model. This study focuses on the INCOMPASS objective to capture
the key surface-atmosphere feedback processes in models, and to evaluate the performance of
data assimilation techniques on monsoon rainfall.

The paper is structured as follows: in Section 2, the model and the experiment design is discussed, while Section 3 illustrates the results. All the results discussed in Section 3 belong to an inner model domain at simulated at 3 km resolution. Finally, conclusions and discussions arising from this study are presented in Section 4.

131 2. Model, Experiment Design and Data

132 **2.1 The WRF model**

The Advanced Weather Research Forecast (WRF-ARW) model version 3.7.1 developed by the 133 National Center for Atmospheric Research (NCAR) and National Center for Environmental 134 Prediction (NCEP) in collaboration with universities is used in this study. The WRF-ARW 135 136 model is a limited area, non-hydrostatic primitive equation model with multiple options for various physical parameterization schemes (Skamarock et al., 2008). Two nested domains with 137 grid resolutions of 9 and 3 km with 35 vertical sigma levels and a model top at 50 hPa are 138 139 considered for this study. The initial and lateral boundary conditions are provided from the National Centre for Environment Protection (NCEP)-Final (FNL) operational global analysis 140 (1° x 1°) grid at a 6-hourly interval. The physics components include the Noah Scheme for land 141 surface processes (Tewari et al. 2004), Rapid Radiative Transfer Model for General Circulation 142 Models (RRTMG) longwave and shortwave radiative transfer scheme (Iacono et al. 2008), 143 MM5 similarity theory for calculating surface heat and moisture fluxes, WRF Double Moment 144 6-class scheme for resolving clouds, and Yonsei University Scheme (YSU) for planetary 145 boundary layer parameterization (Jiménez et al., 2012; Lim and Hong, 2010; Hong et al., 2006). 146 The Kain-Fritsch scheme (Kain, 2003) was used for cumulus convection for the outer domain 147 148 (9 km) while the inner domain is explicitly resolved.

Figure 1. The nested outer (01) and inner (02) WRF domains are shown within the wider South
Asia region. The red circle on the map shows the location of Argul on the map (85.70°E,
20.17°N).

2.2 Experiment design

HRLDAS is an uncoupled land-surface model which runs offline to evolve the land surface
parameters constrained by forcing data from the surface and the above atmosphere (Rajesh et
al. 2016 & 2017; Chen et al., 2007; Nayak et al., 2018). The forcing data used in this experiment
is taken from the Global Land Data Assimilation System (GLDAS) at 0.25° grid and European
Centre for Medium Range Weather Forecasting Interim reanalysis data (ERA-Interim) at 0.75°
grid resolution (bilinear interpolated to 0.25°). Surface parameters such as precipitation,
shortwave and longwave radiation, air temperature, specific humidity and surface pressure are

taken from Global Land Data Assimilation System (GLDAS) datasets, while *u* and *v*components of wind at 10 m are obtained from ERA-Interim (Dee et al., 2011) to be used as
forcing data. The HRLDAS model is first integrated from January 2006 to July 2017 to evolve
land surface parameters over the Indian region. The output land state from HRLDAS is
assimilated into the WRF model initial conditions. Readers are referred to Rajesh et al. (2016,
2017) for a detailed methodology of HRLDAS.

Both CNTL and EHRLDAS experiments are forced with FNL initial and lateral boundary 168 conditions except that EHRLDAS is additionally being forced by the land state (i.e. soil 169 170 moisture and soil temperature) obtained from the HRLDAS. In Table 1, we illustrate three different rainfall events occurring over the Argul location associated with different weather 171 systems. Case 1 is a pre-monsoon isolated thunderstorm event, Case 2 is thunderstorm event 172 173 during the monsoon, while Case 3 is a thunderstorm embedded within a synoptic-scale monsoon depression that occurred in July of 2016. The idea behind considering three rainfall 174 events associated with different weather events is to examine the robustness of HRLDAS in 175 predicting a range of events with heterogeneous origins and different rainfall mechanisms. 176

Table 1.The three cases taken in this study detailing duration and simulation period of theexperiment.

S. No.	Duration (Hours of Prediction)	Expe	eriments
Case 1	0000 UTC 6 – 0000 UTC 7 March 2017 (24 hr)		
Case 2	0000 UTC 30 June – 0000 UTC 1 July 2017 (24 hr)	i)	CNTL
Case 3	0000 UTC 26 June – 0000 UTC 29 June 2016 (72 hr)	ii)	EHRLDAS

179

180

182 **2.3 Validation data**

For validation, surface parameters including rainfall are obtained from an Automatic Weather Station (AWS) installed at Argul (85.680 °E, 20.170 °N). Further, Global Precipitation Measurement (GPM) IMERG satellite rainfall data (Huffman, et al., 2014) is used to validate the spatial distribution of rainfall at 0.25° resolution at half-hourly intervals. In addition, ECMWF Fifth Generation Reanalysis (ERA5) hourly data (Copernicus, 2017) is also used to validate the model-simulated dynamical and thermodynamic parameters.

189 3. Results and Discussions

190 **3.1 Rainfall**

Figure 2(a-f) shows the Equitable Threat Score (ETS) which measures the fraction of observed 191 and/or forecast events that were correctly predicted for all three cases over land and ocean 192 separately. Except for the lowest rainfall threshold (0 - 10 mm), ETS scores are below 0.2 for 193 all simulated cases. Usually in monsoon depression, the rainfall is scattered throughout the 194 domain, but the thunderstorm are isolated and covered a small portion of the domain giving 195 196 such a low skill score. Among these three cases, EHRLDAS experiments show better rainfall 197 prediction skill. The pre-monsoon thundershower case has the lowest skill compared to the other two monsoonal cases. For Case 1, EHRLDAS improves rainfall prediction over the land 198 199 as well as ocean particularly for lower rainfall thresholds (i.e. up to 30 mm), however, the skill over land is poor for Case 2. In Case 3 (monsoon depression), EHRLDAS shows a higher peak 200 for the lowest rainfall threshold (0-10 mm), but the skill remains poor both over ocean and land 201 for higher rainfall thresholds (Figure 2 e, f). This is because the simulations for Case 3 could 202 not capture the pockets of intense rainfall as shown in supplementary Figure S1. We therefore 203 204 highlight that EHRLDAS has outperformed CNTL in rainfall prediction skill except for Case 2. 205

Figure 2. Equitable Treat Score (ETS) for three cases (a-b) Case 1: 6 March 2017, (c-d) Case 2: 30 June 2017 and (e-f) Case 3: 28 June 2016 for land (left column) and sea grid points (right column) respectively. Thresholds 0-10 mm (0 < rainfall <= 10), 10-20 mm includes (10 < rainfall <= 20) and same for other thresholds. ETS is calculated for the 3km inner domain and TRMM data is remapped to the model forecast.

Figure 3(a-f). Day-1 accumulated rainfall (mm) for the first two thunderstorm cases along with
wind at 850 hPa i.e. (a, b, c) for Case 1 and (d, e, f) for Case 2 in model CNTL experiment,
EHRLDAS experiment and GPM/ERA5 observations for the inner model domain,
respectively. The circle marked in the figure represents the location of Argul.

212

217 Figure 3 shows the 24-hour accumulated rainfall for Case 1 and Case 2 along with GPM-IMERG satellite observations, in each case overlaid with 850 hPa winds from the model or 218 ERA5 as appropriate. An anticyclonic flow is seen over the central Bay of Bengal with strong 219 winds near the east coast of India; these features are well replicated by all experiments. There 220 is not much rainfall for Case 1 over the ocean but isolated pockets of convection and rainfall 221 are noted over the land. Further, intense precipitation pockets seen over the east coast and 222 southern peninsular regions of India have been well reproduced in the EHRLDAS experiment. 223 In addition, it is noted that wind speed at 850hPa, particularly of the southerly winds, has 224 increased in EHRLDAS compared to CNTL (Figure 3 b, c), becoming more realistic. The 225

226 spatial distribution of rainfall for Case 2 is shown in Figure 3(e, f, g, h), where CNTL and EHRLDAS are found to feature similar distributions. But interestingly, EHRLDAS produces 227 a better rainfall distribution over land including over the Argul location (circled). The spatial 228 229 distribution of rainfall up to Day 3 is shown in Supplementary Figure S1. It is found that the centre of the low is located over the North Bay of Bengal, which propagates north-westward. 230 In general it is clearly evident that EHRLDAS is able to replicate the observed rainfall 231 232 distribution pattern reasonably well, particularly over the land region even for the isolated premonsoon thunderstorm (Case 1). 233

234 Further location-specific validation of model results is carried out at a station observation location i.e. Argul. Figure 4 (a, b) shows the hourly rain rate from the inner domain for Case 1 235 and Case 2 (for Case 3 AWS data was not available). The nearest four grid points to the Argul 236 237 location in model inner domain are used to linearly interpolate model output and then validated against AWS observations. The observed event durations are marked by the dashed red vertical 238 lines in Figure 4. The improvement in the EHRLDAS simulation can be seen in Supplementary 239 Table 2, showing Pearson Correlation Coefficient (PCC) and Root Mean Square Error (RMSE) 240 calculated over the inner domain for the thunderstorm cases (i.e. Case 1 & 2). It is clearly seen 241 that the EHRLDAS simulations have higher correlation coefficients than CNTL for all surface 242 parameters (rain rate, 2-metre relative humidity, 10 metre wind speed and 2 metre temperature). 243 It is seen that for Case 1, all experiments are able to correctly capture the location as well as 244 245 timing when compared to observations. The rainfall intensity of the thunderstorm episode was not correctly captured by either experiment, although EHRLDAS is closest to observed values. 246 In Case 2, the EHRLDAS captured the event but with a delay of four hours, whereas CNTL 247 248 failed to detect the event over the observation location. Figure 3 (c, d) shows the 10 m wind speed for these two cases. In Case 1, all experiments underestimated the wind speed prior to 249 the event, however the EHRLDAS-simulated time series is closest to observations. 250

251 In general, it is noted that for Case 2, the experiments are not coherent with observations but feature a time lag of approximately four hours, and the wind speed is over-predicted. Further, 252 on examining the temperature and relative humidity (Figure 3 e-h), it is noted that EHRLDAS 253 254 predictions are closest to observed values. In more detail, it is clear that surface air temperature from EHRLDAS closely follows that from observations with a 2-hour time lag. In order to 255 confirm the better performance of EHRLDAS over CNTL, we have examined its moisture 256 transport and vertical velocity characteristics over the location compared to ERA5 257 (Supplementary Figure S2). We found that there is a better resemblance between ERA5 and 258 EHRLDAS compared to CNTL. In general the overestimation in CNTL simulation has been 259 reduced in EHRLDAS. 260

Table 2. Correlation coefficient and Root Mean Square Error for convective Indices (CAPE (J kg⁻¹), CIN (J kg⁻¹), KI (°C), TTI (°C)) for first two thunderstorm cases with respect to ERA5 data and surface parameters (rain rate (mm hr⁻¹), 2m temperature (°C), 2m relative humidity (%) and 10m wind speed (m s⁻¹)) with respect to AWS station at Argul.

	Convective I	ndices(ERA5)	Surface parameters (AWS)					
PCC		CAP	CIN	KI	TTI	Rain	Rel.	10m	2m
		Е				Rate	Hum.	Wind	Temp
Case 1	CNTL	0.7	-0.03	0.57	0.22	0.88	0.88	0.66	0.84
	EHRLDAS	0.8	0.26	0.63	0.45	0.99	0.90	0.73	0.95
Case 2	CNTL	-0.58	0.26	0.57	0.03	-0.07	0.70	-0.02	0.65
	EHRLDAS	-0.31	0.59	0.58	-0.02	-0.08	0.72	0.09	0.78
	1								
RMSE		CAP	CIN	KI	TTI	Rain	Rel.	10m	2m
		Е				Rate	Hum.	wind	Temp
Case 1	CNTL	872	201.5	2.62	2.92	4.91	12	3.1	2.04

	EHRLDAS	705	203.2	3.54	2.53	3.51	11.24	2.48	1.24

	EHRLDAS	661	53.7	1.33	6.14	11.34	19.4	3.48	2.77

265

From these results, we find clear evidence that between the two thunderstorms (pre-monsoon and mature monsoon cases), the pre-monsoon (Case 1) is well predicted by both models with EHRLDAS performing better across a range of fields than CNTL.

Figure 4. Time series of surface parameters (rain rate (mm hr⁻¹), 10m wind speed (m s⁻¹), 2
metre temperature (°C) and 2 metre relative humidity (%)) for the two thunderstorm cases i.e.
(a, c, e, and g) for Case 1 and (b, d, f, h) for Case 2 from CNTL, EHRLDAS and AWS data.
Vertical red lines representing the event duration over Argul (85.70 °E, 20.17 °N).

Figure 5 Time series of sensible heat flux (W m⁻²) and latent heat flux (W m⁻²) over Argul
(85.70 °E, 20.17 °N) for all three cases i.e. (a, b) for Case 1, (c, d) for Case 2 and (e, f) for
Case3 from CNTL, EHRLDAS (calculated from the nearest four grid points linearly
interpolated over Argul location) and AWS data.

279 **3.2 Surface Fluxes and Thermal Indices**

In order to understand exchanges of heat and moisture between the land and atmosphere and 280 281 how they may change with the improved surface initialisation, time series of surface latent (LHF) and sensible heat flux (SHF) over the Argul location are shown in Figure 5. Considering 282 the sensitivity of land surface towards different initial conditions, surface fluxes are analysed 283 here and validated against hourly ERA5 surface fluxes (considering reanalysis data as 284 benchmark, and ERA5 data is remapped to the model grids). A sudden decrease in SHF is 285 shown in all experiments two hours prior to the rainfall peak (Figure 5a, b). This reduction may 286 287 be attributed to an increase of cloud cover leading to reduction of the shortwave radiation and

288 surface temperature resulting in reduced SHF. However, the overestimation (underestimation) of SHF (LHF) with respect to ERA5 is seen for both experiments for Case 1. Most interestingly, 289 LHF patterns simulated by EHRLDAS are closer to ERA5, suggesting the impact of improved 290 291 land state initialisation (soil moisture and temperature) over the location. It is noteworthy to mention that EHRLDAS is able to improve the simulation of this aspect compared to CNTL. 292 Figure 5 (e, f) shows the time series of fluxes for the 72-hour simulation period for Case 3, in 293 294 which it is interesting to note that the model simulations are able to accurately replicate the surface fluxes for the daytime duration, while EHRLDAS is better at simulating their diurnal 295 296 changes. However, we note that for 27 June, both the simulations failed to replicate the diurnal changes in SHF, and the LHF is better represented by EHRLDAS compared to CNTL. 297

Along with the surface fluxes, convective indices associated with thunderstorms are also 298 299 computed and shown in Figure 6 for the first two cases. The major indices such as Convective Available Potential Energy (CAPE), Convective Inhibition (CIN), Total Totals Index (TTI) 300 and K-index (KI) (Williams and Renno', 1993; Miller, 1972; George, 1960) are validated over 301 Argul. The EHRLDAS experiment nicely accumulates CAPE before the occurrence of the 302 thunderstorm for both cases, whereas CNTL failed in this respect (Figure 6a). The enhanced 303 304 magnitude of CAPE seen in Figure 6b is associated with additional LHF into the boundary 305 layer for Case 2; the magnitude of CAPE is very close to that of ERA5, suggesting the robust 306 impact of EHRLDAS (Figure 5a). Further, two more convective indices i.e. TTI and KI are 307 also plotted for these cases in Figure 6 (e, f, g and h). The higher value of KI indicates the occurrence of intense rainfall, when there is abundant moisture through the mid-levels (850 -308 500 hPa), as well as a strong lapse rate. In contrast, TTI takes into account both the static 309 310 stability and the 850 hPa moisture which is very high in case of monsoon depressions. In 311 general it is clearly evident that EHRLDAS is better able to reproduce the actual instability (in terms of magnitude and pattern in ERA5) compared to CTRL. More precisely, a value above 312

313 the threshold of 30 for KI and 44 for TTI (George, 1960; Miller, 1967) indicates an unstable atmosphere as seen in EHRLDAS (Figure 6e, g). In Case 2, the thermal indices have shown 314 higher values than threshold for the entire simulation (may be due to higher moisture 315 convergence in lower atmosphere during monsoon depression situation and reduced lapse rate) 316 , suggesting the inability of convective indices to indicate any significant changes in synoptic-317 scale systems.. During the pre-monsoon season, a high value of the KI indicates favourable 318 conditions for thunderstorms, but high values of KI associated with a synoptic low-pressure 319 system or monsoon depression do not mean conditions for thunderstorm as seen in Figure 6(h). 320 321 The pre-monsoon season is associated with drier troposphere as compared to monsoon depression cases, thus localised effect of convection can bring a variation in KI index but due 322 to high moisture content during monsoon depression it fails to indicate any variation in time 323 324 series.

Figure 6. Thunderstorm indices (CAPE, CIN, TTI and KI) for the first two cases i.e. Case 1 (a, c, e, g) and for Case 2 (b, d, f, h) over the Argul location. (Nearest four grid points are used from inner domain to linearly interpolate over Argul and ERA5 data is remapped to model grid).

330 **3.3 Vorticity**

The convective indices and point-location validation of surface parameters might not comprehensively help in evaluating the impact of EHRLDAS on the monsoon depression (synoptic-scale system). Thus relative vorticity and its components are critically examined over the inner study domain for the 850 hPa pressure level. In this analysis, the vorticity tendency (Dodla and Ratna, 2010) is computed for the whole domain, then the grid points exceeding the 95th percentile of rainfall (i.e., heavy rainfall) are considered for discussion.

337 Equation (vii) indicates the relative vorticity tendency.

 $\frac{\Delta\varepsilon}{\Delta t} = -u\frac{\Delta\varepsilon}{\Delta x} - v\frac{\Delta\varepsilon}{\Delta y} - v\frac{\Delta f}{\Delta y} + f\frac{\Delta w}{\Delta z} - w\frac{\Delta\varepsilon}{\Delta z} + \varepsilon\frac{\Delta w}{\Delta z} + \frac{\Delta u}{\Delta z}\frac{\Delta w}{\Delta y} - \frac{\Delta v}{\Delta z}\frac{\Delta w}{\Delta x}$ 338 (vii) 339 • • • • • • • • . •••• B D Е С \mathbf{F} G Α 340 **A:** relative vorticity tendency (VORTED) 341

342 **B:** horizontal advection (HADV)

- 343 C: vertical advection (VADV)
- 344 **D:** beta term
- **E:** stretching term 1
- **F:** stretching term 2 (STRETCH)

347 **G:** tilting term (TILT)

348 where, ε is relative vorticity, *t* is time step (model output time step, hourly), *f* is the Coriolis 349 parameter, $\Delta x \& \Delta y$ are the horizontal grid spacing (in metres), *w* is vertical velocity (Pa s⁻¹), 350 *u* & *v* are zonal and meridional components of wind.

The values of the various terms A to G of the vorticity equation are computed for each hour for 351 the entire period of simulation. Supplementary Figures S3, S4, S5 show the time series of all 352 the components along with rainfall for the three cases. The VORTED term (vorticity tendency) 353 shows an improvement in EHRLDAS compared to CNTL for Case 1 and in general shows a 354 355 large dependency on vertical advection (VADV). The tilting and stretching terms are found to contribute towards a negative vorticity tendency (anti-cyclonic flow), while horizontal and 356 vertical advection terms are the main contributors to a positive vorticity tendency (consistent 357 with the findings of Yoon and Huang, 2012 for the case 2 and 3. Table 3 shows the correlation 358 of various terms of the vorticity tendency with respect to rainfall. It is seen that the EHRLDAS 359 has increased (bold numbers in the table) the correlation of vertical advection with rainfall for 360 all cases. For Case 2 and Case 3, the improvement in correlation is found for two major terms, 361 i.e. the vertical advection and stretching term, suggesting an enhancement of the relative 362 vorticity in EHRLDAS compared to CNTL. Interestingly, for Case 3, there is no change in 363 364 correlation values as noted for Case 1 and 2. This suggests the smallest contribution from stretching terms to monsoon depression rainfall that is due to the dominant influence of 365 synoptic scale circulation in the system. Further, for cases 2 and 3, EHRLDAS has reduced the 366 magnitude of overestimated contributions of relative vorticity to rainfall as simulated in CTNL 367 (Supplementary Figure S4 and S5). 368

Table 3. Correlation of vorticity tendency equation components with precipitation for the grid
points with precipitation exceeding the 95th percentile, based on hourly data from 24 hours in
Case 1 and Case 2 and 72 hours in Case 3. Number in bold signify the improvement in the
EHRLDAS simulation in VADV term.

Cases	Experiments	HAD	VADV	TIL	STRETC	VORTED	VORTICIT

4. Conclusions

This study investigates the impact of two different land states as initial conditions in the WRF 375 model for two thunderstorm cases (one in the pre-monsoon, Case 1 and one mature monsoon 376 case, Case 2) and one monsoon depression system (Case 3) over the Indian region. For these 377 three cases, different land states are obtained from NCEP Final Operational Global Analysis, 378 FNL (CNTL) and high resolution land data assimilation system (EHRLDAS) at 9 and 3 km 379 380 resolutions respectively. The skill of the rainfall prediction is improved in HRLDAS, 381 particularly for the isolated pre-monsoon thunderstorm (Case 1). In general, EHRLDAS results demonstrate an improved prediction of rainfall by capturing high intense rainfall pockets and 382 the associated stronger winds, particularly over the coastal region. These strong winds are 383 384 closer to the ERA5 re-analysis, suggesting an improved land-ocean thermal contrast in EHRLDAS. In addition, the location-specific representation of thermal indices of convection 385 386 and surface fluxes are better represented by EHRLDAS in all cases. It is seen that EHRLDAS is able to capture the localised instability conditions (thermal indices) more distinctly over 387 coastal eastern India (i.e. Argul) prior to (up to 2 hours lead time) the occurrence of rain from 388 the pre-monsoon thunderstorm compared to the other two cases (Cases 2 & 3) which are 389

390 embedded within the large-scale influence of the monsoon circulation. Overall, for the pointlocation validation, EHRLDAS shows more resemblance with ERA5 in terms of fluxes, CAPE 391 and CIN for all cases compared to CNTL. Further, the components of the vorticity tendency 392 393 equation are computed for those grid points featuring heavy rainfall (> 95th percentile). In general, results suggest that enhancement of vertical advection primarily contributes towards 394 the positive vorticity tendency in these convective systems and particularly for the pre-395 396 monsoon thundershower. Thus EHRLDAS has shown enhanced correlation of the vertical advection term with precipitation for cases 1 and 2. 397

398 We clearly found that better land initialisation is useful for improving the representation of local convective and dynamical processes, which are crucial for better prediction of rainfall 399 400 particularly over coastal east India. This therefore conveys the need for incorporating an 401 accurate land-surface state in the initial conditions of numerical models to improve rainfall 402 prediction skill, especially at very high resolution (3 km). Further, we highlight that EHRLDAS shows better representation of convective indices of localised and synoptic-scale severe 403 404 weather events. Further work would be needed to perform a more comprehensive analysis of pre-monsoon and monsoon storms, for example by systematically comparing day-1 forecasts 405 406 of all days through spring and summer seasons using this modelling framework.

407 Acknowledgement

The authors would like to thank Indian Institute of Technology Bhubaneswar for providing research facilities and helpful assistance required for this purpose. Further, our gratitude to funding agency Indian Institute of Tropical Meteorology (IITM) for providing the financial assistance to carry out this work under Ministry of Earth Science's "INCOMPASS" project (RP-083), Council of Scientific and Industrial Research (CSIR) RP-104, Science and Engineering Board (RP-193). The work of INCOMPASS in the UK was funded by NERC (grant numbers NE/L013886/1 and NE/P003117/1). We are grateful to the National Centre for 415 Atmospheric Research (NCAR), ECMWF and National Aeronautical and Space
416 Administration (NASA) for models and data sets used to carry out this study.
