Supplementary Methods

UK Biobank

UK biobank participants were aged 37 to 73 years when first recruited in one of the 22 assessment centres between years 2006 and 2010 (Allen et al., 2012). Participants' baseline information was collected using touchscreen questionnaires, verbal interview, physical examination, and biological samples, including blood, saliva and urine (Hewitt, Walters, Padmanabhan, & Dawson, 2016). Information on health status and hospital admissions is available through linkage to Hospital Episode Statistics (HES) (Biobank, 2013).

Genetic information is available for all UK Biobank individuals (Bycroft et al., 2018). Genotyping was performed using two closely related arrays – UK BiLEVE array (for 50 000 individuals) and UK Biobank Axiom array (for 450 500 individuals). Each array contains 800 000 markers with 95% similarity in content (Bycroft et al., 2018). UK Biobank imputes variants using reference panels from the Haplotype Reference Consortium and UK10K + 1000 genomes. Details of methodology for genotyping, imputation and quality control can be found elsewhere (Bycroft et al., 2018).

BMI and other anthropometric measures

Using a standard procedure, a trained nurse measured height, weight, waist circumference (WC) and other anthropometric measures of the participants during the baseline assessment (Biobank, 2014). Participant's height was measured to the nearest centimetre with a Seca 240 height measure, without shoes. Weight was measured to the nearest 0.1 kg using the Tanita BC-418 MA body composition analyser after removal of shoes and heavy clothes (Biobank, 2014). Measured weight (kg) and height (m) were used to derive BMI (kg/m^2). Individuals with a BMI greater than or equal to $30kg/m^2$ were grouped as those with obesity, and those below 30 kg/m^2 were grouped without obesity (WHO, 2016). Waist circumference was measured using Seca 200cm tape around the smallest part of the trunk when the individuals exhaled (Biobank, 2014). Bioimpedance data including body fat percentage (BFP) was obtained from a Tanita BC418MA body composition analyser (Biobank, 2014).

Socioeconomic and lifestyle covariates

In addition to age, sex and assessment center, we considered a range of lifestyle and socioeconomic factors as potential confounders (Sudlow et al., 2015). These variables were self-reported during the baseline assessment, with the exception of the Townsend deprivation index, which was obtained from the local National Health System Primary care trust registries ("UK Biobank "). Townsend deprivation index is an area-based score generated by including four census variables: no-car ownership,

overcrowding, no-house ownership, and unemployment (Phillimore, Beattie, & Townsend, 1994). Educational status was based on highest qualification and grouped as “none”, “A-levels and below” and “degree or professional”. Sedentary behaviour was based on a questions on daily time spent watching TV, using a computer, and driving, with information on these three questions combined to a single indicator and classified as ”less than five hours” vs. “five hours or more”. Participants were also asked about the number of days they had spent at least 10 minutes at a time walking, or undertaking moderate and vigorous activities, and each type of activity was grouped as “not at all”, “one to four days”, and “five to seven days”. To adjust for the quality of diet, we included the average daily consumption of fruit, vegetables and salad. Further adjustments included smoking (“never”, “previous”, and “current”), alcohol consumption (“never”, “previous”, and “current”), and general health status (“excellent”, “good”, “fair”, and “poor”). Information on antidepressant medication use (“yes” and “no) was based on self-reported regular use of prescription medications, and included selective serotonin reuptake inhibitors (SSRI), tricyclic antidepressants (TCA), monoamine oxidase inhibitors (MAOI) and others ("UK Biobank ").

Statistical analysis

Mendelian randomisation (MR): Since the genetic variants, that used as an instrument for the exposure (in our case:- depression), are randomly allocated during conception, and this allele segregation occurs before any of the factors affecting the exposure and outcome exist, the common limitations (confounding and reverse causation) of observational studies can be largely avoided (Zheng et al., 2017). Primarily MR used one-sample analysis within the UK Biobank and for sensitivity analysis, several two-sample MR approaches were performed. The one-sample MR analysis included a first stage logistic regression of depression against the GRS_{MDD}. Using the predicted probability values (converted to log odds) from the first regression, the second regression (linear) analysis was completed against BMI. Both stage analyses included adjustment for age, sex, assessment centre, genotyping array and 15 principal components. Coefficient derived from the second regression analysis indicates the causal estimates. A sensitivity analysis using three two-sample MR analysis approaches were performed. Firstly, inverse-variance weighted regression, which is regression of gene-outcome estimates on gene-exposure estimates with the intercept constrained at zero (Burgess, Butterworth, & Thompson, 2013). This analyses give a reliable estimates if there is no unbalanced horizontal pleiotropy. Second, MR-Egger which is the weighted regression of gene-outcome estimates on gene-exposure estimates with an intercept unconstrained at zero (Bowden, Davey Smith, & Burgess, 2015). MR-Egger is robust for directional pleiotropy but should fulfilled a weaker assumption called the InSIDE assumption (the correlation between gene-exposure estimates and the pleiotropic effect [the direct effect of genetic variants on outcome] is zero) (Bowden et al., 2015). Under the fulfilment of InSIDE assumption, the slope from the weighted regression of gene-outcome on gene-exposure provides the causal estimates while an intercept significantly different from zero indicates the presence of directional pleiotropy (Bowden et al., 2015). The third MR-analyses methods (weighted median-based MR) does not require the InSIDE assumption and give a reliable estimates if at least

half of the genetic variants are valid instruments (i.e. reliable event though half of the genetic variants are pleiotropic) (Bowden, Davey Smith, Haycock, & Burgess, 2016).

Supplementary table 1. Association with MDD for the 44-MDD variants used to construct the genetic risk score in the UK Biobank and the PGC consortium meta-analysis.

SNP: Single nucleotide polymorphism. Chr.: Chromosome. † Imputation quality was poor for all the six variants (info score ≤0.89 and MAF≤0.01), hence we replaced them with a proxy variant. ‡ These indicate SNPs with two alternative rs-numbers: rs116755193 for rs34660260, and rs115507122 for rs3095337. UKB: UK Biobank; PGC: Psychiatric genetic Consortium; EAF: Effect allele frequency; and P_HWE: P-value for Hardy-Weinberg Equilibrium test.

Single nucleotide polymorphism (SNP) in **bold** are neuronal otherwise non-neuronal SNP

UKB: UK Biobank; GIANT: **G**enetic **I**nvestigation of **AN**thropometric **T**raits; EAF: Effect allele frequency; and P_HWE: P-value for Hardy-Weinberg Equilibrium test

SNPs have been selected based on genome-wide association analyses on BMI in the GIANT consortium (Locke et al, 2015) not including the UK Biobank.

† Estimates in UKB from models adjusted for age, age square, sex, assessment centre, type of genotyping array, and 15 principal components; GIANT estimates adjusted for age, age square, and study-specific covariates (for example, genotype-derived principal components).

Supplementary table 3. Association between BMI genetic risk score (or rs6567160 variant near *MC4R* gene) and different anthropometric measures among individuals with and without depression
