37 IMPLICATIONS FOR PRACTICE

38	•	Consideration of soil microbiota in mine site rehabilitation and restoration is
39		important for returning functional, self-sustaining biodiverse ecosystems and
40		improving restoration practices.
41	•	Bacterial community variation can be high among reference sites which
42		highlights the need for appropriate sampling design in assessing soil microbial
43		recovery trajectories.
44	•	Our study shows how changes in bacterial communities across a restoration
45		chronosequence can be routinely monitored to provide insights into the
46		recovery of soil microbiota towards restoration targets.
47		

48 **ABSTRACT**

Mining activities modify both above- and below-ground ecological communities, 49 presenting substantial challenges for restoration. The soil microbiome is one of these 50 impacted communities and performs important ecosystem functions but receives 51 limited focus in restoration. Sequencing soil DNA enables accurate and cost-52 effective assessment of soil microbiota, allowing for comparisons across land use, 53 54 environmental, and temporal gradients. We used amplicon sequencing of the bacterial 16s rRNA gene extracted from soil samples across a 28-year post-mining 55 56 rehabilitation chronosequence to assess soil bacterial composition and diversity following rehabilitation at a bauxite mine in Western Australia's jarrah forest. We 57 show that while bacterial alpha diversity did not differ between reference and 58 59 rehabilitated sites, bacterial community composition changed dramatically across the chronosequence, suggesting strong impacts by mining and rehabilitation activities. 60 Bacterial communities generally became increasingly similar to unmined reference 61 62 sites with time since rehabilitation. Soil from sites rehabilitated as recently as 14 years ago did not have significantly different communities to reference sites. Overall, 63 our study provides evidence indicating the recovery of soil bacterial communities 64 towards reference states following rehabilitation. Including several ecological 65 66 reference sites revealed substantial natural variability in bacterial communities from 67 within a single mine site. We urge future restoration chronosequence studies to sample reference sites that geographically span the restored sites and/or are 68 spatially paired with restored sites to ensure this variability is captured and to 69 70 improve any inferences on recovery.

71 **INTRODUCTION**

The global mining sector is reliant on access to mineral deposits and expansions into 72 intact biodiverse ecosystems (Stevens & Dixon 2017). In Australia, it is estimated 73 that mining has impacted approximately 10 million hectares of land (Grant 2009). 74 Mining activities extensively modify landscapes, directly impacting on both above-75 (e.g., animal, plant) and below-ground ecological communities (e.g., soil microbiota) 76 77 (Banning et al. 2011; Stevens & Dixon 2017; Kneller et al. 2018). These often-severe ecosystem impacts present challenges in restoring or rehabilitating biodiverse and 78 79 functional ecosystems (Doley et al. 2012; Tibbett 2015). Indeed, as the ecological impacts of mining continue to grow, so does the need for improved understanding of 80 how best to repair the damage done. 81

82

Restoration projects have tended to focus on recreating aboveground plant 83 communities, often overlooking soil biodiversity (Heneghan et al. 2008; Farrell et al. 84 85 2020). However, there is increasing attention paid to soil biodiversity and plant-soilbiota relationships, which has largely been enabled by DNA sequencing 86 technologies (Breed et al. 2019). The important role of soil in ecological restoration 87 has long been known, especially regarding physical and chemical processes such as 88 89 nutrient cycling and soil formation (Heneghan et al. 2008; Kardol & Wardle 2010). 90 However, soil microbiota (i.e., communities of bacteria, archaea, eukaryotes) and their interactions within the soil system and with aboveground biota have received 91 less attention (Harris 2009; Eisenhauer et al. 2017; Mendes et al. 2019). The 92 question of whether soil microbial communities recover following aboveground 93 revegetation is still unclear, with some observational studies finding a transition 94 towards reference ecosystem states (e.g., Barber et al. 2017; Gellie et al. 2017), 95

while others have found either that recovery had stalled (e.g., Farrell et al. 2020;
Lem et al. 2022) or recovery is dependent on organism or topsoil handling methods
(Van der Heyde 2020). This presents a problem since soil microbiota are highly
diverse and functionally important ecosystem components and therefore
understanding their ecology and responses to both impacts and restoration or
rehabilitation is integral to ecosystem restoration (Cameron et al. 2018; DelgadoBaquerizo et al. 2020).

103

104 Surface strip mining results in strong and long-lasting impacts on soil biotic and abiotic properties, including decreases in soil microbial activity and organic matter 105 106 content, and changes in pH and salinity levels (George et al. 2010; Lewis et al. 2010; 107 Sheoran et al. 2010; Banning et al. 2011). These impacts can be driven by the removal and stockpiling of topsoils for extended periods of time, which can expose 108 soils to high temperatures and subsequent drying (Golos & Dixon 2014). Although 109 110 best practice for the rehabilitation of surface mining is to directly return topsoil, and 111 where necessary, stockpile soil for the shortest time possible (Rokich et al. 2000; Tibbett 2010; Lewis et al. 2010; Spain et al 2015) In reality, topsoils are still routinely 112 stockpiled for extended periods before being used to restore mine sites (Golos & 113 114 Dixon 2014; Ngugi et al. 2018). While the intent of this 'direct return' process is to 115 limit the impact of the mining process on soil properties, how the biological properties 116 of soil respond following direct return of topsoil and subsequent rehabilitation is still unclear. 117

118

While the potential use of soil microbiota as an ecosystem indicator is beginning tobe explored as part of an interrelated matrix of biotic and abiotic ecosystem

121 components (Muñoz-Rojas 2018; Tibbett et al. 2019), cause and effect relationships regarding the response of soil microbiota post-rehabilitation and specific drivers of 122 any recovery remains a notable knowledge gap (Lem et al. 2022). A pragmatic 123 approach to begin to understand changes in microbiota with rehabilitation has been 124 to use space as a proxy for time using a rehabilitation chronosequence design (i.e., 125 sampling across a series of similar sites with different times since rehabilitation), and 126 127 there are examples of this type of study in a post-mining context (Ngugi et al. 2018; Schmid et al. 2020; van der Heyde et al. 2020). Chronosequence studies provide an 128 129 efficient approach to study the effect of time as an alternative to long-term 130 longitudinal sampling (Walker et al. 2010). However, spatial and temporal confounding factors (e.g., spatial and/or temporal variation in soil, climate and 131 132 rehabilitation methods), can impact inferences made from chronosequence studies (Pickett 1989; Fleming 1999). With variation of soil microbial communities being so 133 scale dependant (Martiny et al. 2011; Fierer 2017), how spatial variability among 134 135 reference sites impacts inferences from these chronosequence studies, and particularly regarding rehabilitation targets and completion criteria (Manero et al. 136 2021), needs to be assessed. 137

138

Recent advances in DNA sequencing technologies have enabled improved
assessments of whole communities of soil microbiota compared to historical culturedependent methods (Thompson et al. 2017; Breed et al. 2019; Berg et al. 2020;
Nkongolo & Narendrula-Kotha 2020). One such method is to use high-throughput
sequencing to generate amplicon datasets, which can be used to compare the
diversity and composition of targeted microbial groups (e.g., bacteria) across
different environmental conditions, locations, land uses, rehabilitation interventions,

146	or chronosequences to determine how soil microbial diversity and community
147	composition may be impacted (Fierer et al. 2012; Thompson et al. 2017; Breed et al.
148	2019; Tedersoo et al. 2019). Here, we used sequencing of the bacterial 16s rRNA
149	gene from soils collected across a 28-year rehabilitation chronosequence to
150	investigate the recovery trajectories of soil bacterial communities with time since
151	rehabilitation at a bauxite mine site in Western Australia's northern jarrah
152	(Eucalyptus marginata) forest. Given the extreme impact of the bauxite mining
153	process on pre-disturbance soils (George et al. 2010), we expect the bacterial
154	communities in the newly rehabilitated sites to be least similar to those of reference
155	sites, with a successional trend of increasing similarity with time. We address the
156	following research questions:
157	1. Does soil bacterial diversity and community composition differ between
158	rehabilitated sites and unmined reference sites?
159	2. How variable are bacterial communities across multiple reference sites that
160	geographically span the mine site?
161	3. Does the soil bacterial community change through the chronosequence with
162	communities in older rehabilitated sites becoming more like those found in
163	reference sites?
164	4. Do changes in soil bacterial communities associate with changes in soil
165	abiotic properties across the chronosequence?
166	Our study improves understanding of changes in soil bacterial communities over
167	time following mine site rehabilitation and helps to enable rehabilitation practitioners
168	to better consider soil bacteria in their interventions. Further, we highlight the
169	variation of bacterial communities across our six reference sites pointing to the need

to account for spatially dependent factors through appropriate experimental design

and reference site selection in chronosequence-based restoration studies.

172

173 METHODS

174 Study site and soil sampling

This study was conducted at the Worsley Alumina mine in southwest Western 175 176 Australia (Fig. 1) where bauxite has been mined since 1984. Mining and rehabilitation work are ongoing, with approximately 5900 hectares of land cleared for 177 178 mining and 3200 hectares rehabilitated to date. The mine is located in northern 179 jarrah (Eucalyptus marginata) forest within the Southwest Australian Floristic Region, an international biodiversity hotspot (Myers et al. 2000). The northern jarrah forest is 180 181 a dry sclerophyllous open forest or woodland dominated by jarrah (E. marginata) and marri (Corymbia calophylla) trees with a diverse understory dominated by species 182 from the Fabaceae, Asteraceae, Proteaceae, and Myrtaceae families (Koch & 183 184 Samsa 2007). Soils within the mine are sandy-gravel, lateritic (high in aluminium and iron), nutrient poor, and slightly acidic. The mine site has a Mediterranean-type 185 climate with dry hot summers and cool wet winters and a mean annual rainfall of 505 186 mm (Australian Bureau of Meteorology, 2021). 187

188

The mining process at this site first involves removal of all vegetation and topsoil, then overburden is stripped away to access the bauxite ore. Long term (>3 months) topsoil storage for rehabilitation is limited where possible. Instead, the preferred practice is for the 'direct return' of topsoil from donor locations (e.g., newly mined areas) to a previously mined area. Following bauxite extraction, mined areas are first contoured to reflect surrounding topography using non-ore and gravel material, and

then topsoil is spread to a minimum depth of 10 cm before being furrowed and
seeded with a mix of local native plant species. This plant species mix has increased
from 40 species in 1994 to over 200 by 2015 to better represent the diverse natural
floral diversity of the sites prior to disturbance.

199

For our study, soil sampling occurred between October and December 2019 as part 200 201 of the Australian Microbiome (AM) Initiative, following the protocols of the Biomes of Australian Soil Environments (Bissett et al. 2016). Sample sites were chosen, as far 202 203 as practicable, to provide an even distribution of sampling locations covering the spatial extent of mining activities and sites of varying rehabilitation age (Fig. 1). We 204 were also conscious of the need to evenly distribute sampling locations to limit the 205 206 effect of spatial autocorrelations. Six uncleared reference sites that were largely embedded within and throughout the mine area were selected to compare with the 207 208 rehabilitated sites, and to capture natural spatial variation in bacterial communities 209 across the mine site. Restored sites included: two from 1991, four from 1996, two 210 from 1999, two from 2002, two from 2005, one from 2007, three from 2011, and three from 2017 (n = 25 sites in total). Sites rehabilitated in 2017 were rare within the 211 main mine area, forcing samples to be taken from two sites rehabilitated in 2017 and 212 213 an adjacent reference site, from a spatially separate area approximately 4km away 214 from the main sampling sites.

215

In each site, soil was sampled from two depths (0-10 cm and 20-30 cm) where each
sample represented a composite from nine subsamples systematically chosen to
represent site heterogeneity within 25 x 25 m plots. The nine subsamples from each
depth were pooled into a sterile plastic bag, and then homogenised. From each

220 pooled sample, a 500 g subsample of soil was taken for physicochemical analysis and a 50 mL subsample for DNA extraction. Soil chemical analyses were performed 221 222 at CSBP Laboratories (Perth, Western Australia) to quantify soil organic carbon, 223 ammonium, potassium, sulphur, calcium, pH, nitrate, and phosphorous. The 50 mL sample was frozen on-site and sent packed on dry ice to the Australian Genome 224 Research Facility (AGRF) in Adelaide, South Australia for DNA extraction (described 225 226 below). Each replicate had GPS coordinates and a panoramic photograph taken 227 (Fig. S1).

228

229 DNA extraction, sequencing, and bioinformatics

DNA was extracted from each sample in triplicate using the Qiagen DNeasy 230 231 Powerlyzer Powersoil Kit following manufacturer's instructions and quantified fluorometricly. Soil bacterial 16S rRNA was amplified using the 27F (Lane 1991) and 232 519R (Lane et al. 1985) primer set before sequencing (300bp PE) on the Illumina 233 234 MiSeg platform. Sequence data used for this work was generated by the Australian 235 Microbiome using their amplicon analysis workflow (Bissett et al. 2016) (https://www.australianmicrobiome.com/protocols/16sanalysisworkflow/) and were 236 downloaded as amplicon sequence variant abundance tables from the AM portal (12 237 238 Aug. 2020) (https://www.australianmicrobiome.com/; samples 102.100.100/138358-239 138407). Paired end reads were merged using Flash2 (Magoč & Salzberg 2011), 240 merged sequences were then further screened to remove those with ambiguities. long homopolymer runs, or too short/long using Mothur screen.seqs (Schloss et al. 241 242 2009). Reads passing filter were dereplicated and denoised to zero radius operational taxonomic units (zOTU) using the UNOISE3 algorithm (Edgar 2016) in 243 244 USEARCH (Edgar 2010). All reads were then mapped to zOTUs to construct a

zOTU by read count table. zOTUs were assigned taxonomy with the RDP Bayesian
classifier (Wang et al. 2007) and the SILVA v132 rRNA database (Quast et al. 2013;
Yilmaz et al. 2014; Glöckner et al. 2017). zOTUs not classified as "Bacteria" or
classified as "Bacteria_unclassified" at the phylum level were discarded, along with
those classified "Mitochondria" or "Chloroplast". zOTUs which did not occur in at
least two samples were also discarded to avoid unrepresentative taxa.

251

252

253 Data analyses

254 R version 4.0.2 (R Core Team, 2020) was used for all downstream statistical analyses. Rarefaction curves were generated comparing observed zOTU richness 255 256 and Shannon diversity against sample sequence read depth to assess if sample diversity was adequately represented by read depth, as well as to determine an 257 appropriate read depth for rarefaction (Fig.S2). Two samples (one 20-30 cm deep 258 259 reference site and one 20-30 cm deep 2017 site) were found to have low sequence 260 read depths (80 and 28,854 reads respectively) and were removed from analysis. 261 The remaining samples were rarefied to the lowest remaining sample read depth (n = 54,840 reads) using the rarefy even depth function in Phyloseg (McMurdie & 262 263 Holmes 2013) to ensure unbiased comparisons across samples. zOTUs that were 264 not present in at least two samples were discarded to avoid non-representative taxa. 265

266 Bacterial diversity and community composition

267 We calculated observed bacterial zOTU richness, and estimated Chao1 richness,

268 Gini-Simpson (Simpson), and Shannon-Weiner (Shannon) diversity indices using

269 *phyloseq* to assess any differences in sample (*alpha*) diversity through the

chronosequence. These diversity data were compared across year of rehabilitation
separately for each depth using permuted analysis of variance with the *aovp* function
in *Imperm* v2.1.0 (Wheeler et al. 2016) with 5000 permutations.

273

To explore differences in bacterial community composition across the 274 chronosequence, variation in bacterial community composition (beta diversity) 275 276 across depth and year of rehabilitation was visualised with non-metric multi-277 dimensional scaling (NMDS) ordinations of Bray-Curtis distances from the rarefied 278 zOTU abundances using *ordinate* in *phyloseq*. Differences in bacterial community 279 composition across depth and year of rehabilitation were assessed using permuted multivariate analysis of variance (PERMANOVA) implemented with the adonis2 280 281 method in vegan (Oksanen et al. 2013). To account for the repeated measure of two depths in soil sampling, we implemented a nested design with our PERMANOVAs 282 with the *setBlock* function to constrain the permutations by a dummy variable 283 284 accounting for depth as a repeated measure. Homogeneity of group dispersions was tested with the betadisper function in vegan. 285

286

To evaluate the trajectory of bacterial communities in rehabilitated sites towards 287 288 reference sites and establish how varied bacterial communities are among multiple 289 unmined reference sites, we used Bray-Curtis distances to assess the 'similarity to 290 reference' for each sample. This involved calculating similarity values (i.e., 100%*(1 291 - distance)), for each sample to all reference samples, including each reference 292 sample to all other references (Liddicoat et al. 2022). The distribution of similarity to reference values across the different years of rehabilitation were then displayed as a 293 294 series of boxplots. A Kruskal-Wallis multiple comparison test was used to determine

whether the similarity to reference of samples changed with year of rehabilitation,
and any significant differences between rehabilitation years were identified using
post-hoc Dunn tests with Bonferroni correction to adjust *p* values for multiple
comparisons. Heatmaps of the relative abundances of bacterial phyla, class, and
order from non-rarefied zOTU data created with the *plot_heatmap()* function in *phyloseq* were used to visualise if any particular taxa were driving changes in
community composition through the chronosequence for each depth.

302

303 Soil chemical associations

Associations between bacterial community composition and scaled (i.e., mean-304 centred and divided by the standard deviation) soil chemical variables across the 305 306 chronosequence were visualised and assessed with constrained correspondence analysis (CCA) with the ordiR2step() function in vegan separately for each depth. 307 Highly correlated (>0.75) variables were identified (ammonium and potassium at 0-308 309 10 cm and calcium at 20-30 cm) and removed using the *findCorrelation()* function in 310 *caret* (Kuhn 2015). Model-selected soil variables were tested for significance with permuted ANOVA with 999 permutations. Nitrate and phosphorous variables were 311 not included in analysis as they returned below-threshold measurements for multiple 312 313 samples. Differences in each soil chemical variable across the chronosequence 314 were assessed with Kruskal-Wallis tests, and Dunn post-hoc tests with Bonferroni 315 corrections and visualised in a series of scatterplots for each soil depth.

316

317 Spatial autocorrelation

We investigated the association between bacterial community composition (using Bray-Curtis ecological distances) and geographic distances between replicates to

test for the presence of spatial autocorrelation. Here, we used Haversine distance
matrices for each depth using the *distm* function in *geosphere* (Hijmans et al. 2017),
which calculates the distance between every sample based on a spherical land
surface from GPS coordinates. The relationship between the Haversine distance
matrix and Bray-Curtis distance matrix was examined via a Mantel test in *vegan*using the *spearman* method with 9,999 permutations.

326

327 **RESULTS**

A total of 4,192,984 bacterial 16s rRNA reads were generated across the 50 samples, which spanned the two soil depths across the 28-year rehabilitation chronosequence. There were 70,199 unique bacterial zOTUs identified with a mean of 83,859 ±19,546 SD sequence reads per sample (Table 1). Following quality filtering and rarefaction to the lowest sample read depth of 54,840 reads, 65,098 unique zOTUs remained for analysis across the remaining 48 samples.

334

335 Bacterial diversity and community composition

336 Bacterial community composition varied significantly by soil depth and year of

rehabilitation (Fig. 2; PERMANOVA: depth df=1, F=7.170, *p*=0.005; year df=8,

F=2.3462.02, *p*=0.005). Community composition in rehabilitation sites became

increasingly similar to reference sites with time since rehabilitation (Fig. 3). Bray-

340 Curtis similarity to reference values showed significant variation (Kruskal-Wallis: 0-10

341 cm p<0.001, 20-30 cm p<0.001) and post-hoc Dunn tests with Bonferroni correction,

- at both the 0-10 cm and 20-30 cm depths (Fig. 3), indicated younger rehabilitation
- 343 sites were significantly different to reference sites, while older rehabilitation sites
- 344 were not different to reference sites. The median among reference site similarity

345 (similarity of each reference site to all other reference sites) was 40% in 0-10 cm soils and 47% in the deeper 20-30 cm soils. At both depths, younger sites that 346 differed to reference sites and had 10-15% lower median similarity to reference 347 values than the among reference site similarity values. Year of rehabilitation had no 348 effect on observed zOTU richness, Chao1 estimated, Simpson, or Shannon diversity 349 metrics at either soil sample depth (permuted ANOVA: p> 0.05 in each case; Table 350 351 2, Fig. S3). Heatmaps of bacterial phylum, class, and order for both sample depths are presented as supplementary data in Figures S6-S11. 352

353

354 Soil chemical associations

At the 0-10 cm depth, CCA model selection indicated bacterial community 355 356 composition associated with both pH, which decreased with age, and organic carbon, which increased with age (Fig. 4, Fig. S4). Tests of significance of the terms 357 indicated by CCA with showed no evidence of significance for pH (permuted 358 ANOVA: df=1, F=1.205, p=0.062) but strong evidence for organic carbon (permuted 359 ANOVA: df=1, F=2.07, p=0.001). Although not associated with changes in bacterial 360 communities across the chronosequence, calcium, potassium, sulphur, and 361 ammonium all saw increases with age in the 0-10 cm soil profile (Fig. S4). At the 362 deeper 20-30 cm depth pH was the only CCA model selected soil variable that 363 364 associated with bacterial communities across the chronosequence (permuted ANOVA: df=1, F=1.349, p=0.014, Fig. 4) and pH decreased with age (Fig. S4). No 365 soil chemical variable significantly varied by year of rehabilitation at either sample 366 367 depth following Bonferroni corrections for multiple tests (p>0.05 in all cases, Fig. S4). 368

369 Spatial autocorrelation

370 Analysis of Bray-Curtis ecological distances representing bacterial community composition, and the geographic distances between samples showed a significant, 371 372 though weak, spatial autocorrelation (Mantel test: r=0.231, p=0.012; Fig. 4a) 373 indicating that geographic distance between samples associated with differences in bacterial community composition. To explore if this spatial autocorrelation was being 374 driven by three sites that were geographically separate from all other sites (Fig. 1), 375 376 we removed these and reran the Mantel test which resulted in no significant correlation (Mantel test: r=0.081, p=0.162; Fig. 4b). 377

378

379 **DISCUSSION**

Here we quantified variation in soil bacterial communities across a 28-year 380 381 rehabilitation chronosequence following rehabilitation of a bauxite mine site in Western Australian jarrah forest. There was a clear association of bacterial 382 community composition with age of rehabilitation, where older sites were more like 383 384 reference sites than younger sites. In the shallow soils (0-10cm), we found strong 385 evidence of bacterial community composition in sites rehabilitated as recently as 2002 (17 years old) being as similar to the reference sites as the reference sites 386 were to each other. In the deeper soils (20-30cm), this trajectory towards reference 387 site bacterial community composition appeared somewhat slower, potentially 388 389 exacerbated by the higher among reference median similarity of 47% compared to 390 40% in the shallow soils. These biologically important trends with increasing age reflect a successional transition in the structure of bacterial communities, where 391 392 communities in rehabilitated sites increasingly resembled those from unmined reference sites with increased time since rehabilitation. Although community 393 394 composition was associated with rehabilitation age, we observed no effect of

395 rehabilitation age or soil depth on bacterial alpha diversity. Our findings show that while the mining process impacts bacterial communities even with direct return of 396 397 topsoil, these communities can respond rapidly to environmental changes following 398 rehabilitation. This relatively rapid change can provide an early indication of ecosystem recovery trajectories moving toward the reference ecosystem (Banning et 399 al. 2011; Yan et al. 2019). Together, these results indicate that ecologically important 400 401 soil bacterial communities are on a trajectory towards recovery following 402 rehabilitation techniques applied at the Worsley Alumina bauxite mine.

403

We observed associations between changes in soil pH with bacterial community 404 structure at both sampled soil depths. Globally, soil pH is among the strongest 405 406 drivers of soil bacterial community composition at local and broad spatial scales 407 (Fierer 2017). However, these effects may not be as clear across narrower ranges of pH. At both depths soil pH decreased with time since rehabilitation, but in the deeper 408 409 soils pH trended away from the pH of reference sites. This negative association 410 between pH with time since rehabilitation at this soil depth could be impacting on 411 deeper soil bacterial community composition and may be a barrier to future bacterial community recovery. This highlights the importance of targeting ideal site-specific 412 413 soil pH levels for microbiota in mine rehabilitation and may be an avenue to 414 investigate the potential to shorten recovery time frames by optimising soil pH earlier 415 in the rehabilitation process.

416

Soil organic carbon also associated with bacterial communities in the 0-10 cm soil
samples, increasing with time since rehabilitation and becoming more like the
reference sites. Like pH, soil organic carbon is one of the most important abiotic

factors in structuring soil bacterial community composition (Fierer 2017) and soil
organic carbon is a key indicator of soil quality (Muñoz-Rojas 2018). Soil organic
carbon is expected to accumulate more rapidly in surface soils compared to deeper
soils due to the build-up of detritus on the surface. This change in abiotic soil
properties is likely to have driven the rapid development of contrasting bacterial
community composition depth profiles between our two sample depths to some
degree.

427

428 Soil chemical properties have large effects on the composition and diversity of soil 429 bacterial communities (Fierer 2017; Bahram et al. 2018; Delgado-Baguerizo & 430 Eldridge 2019). Although bauxite mining is known to impact soil abiotic properties 431 such as calcium, phosphorous, potassium, and aluminium (George et al. 2010; 432 Lewis et al. 2010), we did not observe significant differences in these variables across different years of rehabilitation in our chronosequence. The absence of 433 434 differences in these abiotic properties could potentially be explained by decreased 435 impacts of direct soil return procedures that are employed at this site, compared to more common soil stockpiling practices. However, more research is required to 436 better understand the factors that are driving the observed soil chemistry variation. 437 438

Although depth explained more variation in bacterial community composition than
time since rehabilitation, the recovery trajectory with time is similar across both
depths with bacterial communities in rehabilitated sites becoming increasingly like
reference sites with time. Even with the homogenisation of soil that occurs with direct
return or storage of topsoils, our youngest sites still developed depth profiles in as
short as two years following rehabilitation. This stratification of bacterial composition

across soil depth is thought to result from differential availability of macronutrients 445 and organic carbon and/or differing environmental gradients across soil depths 446 447 (Allison et al. 2007), and both these trends are supported by our results that generally show lower nutrient levels in the deeper soils. Our results support recent 448 soil genomic research that show variation in bacterial community composition 449 between soil depths as well as directional trends of community composition with time 450 451 since rehabilitation (Gellie et al. 2017; Yan et al. 2019). While these results indicate a recovery trajectory of bacterial communities returning to their pre-disturbance 452 453 condition with time since rehabilitation, ascertaining whether soil edaphic variables, aboveground plant communities, or other factors are specifically driving this recovery 454 455 is still unclear.

456

While chronosequence studies can be used to examine the effect of time following 457 rehabilitation, changes to rehabilitation practices over time such as soil handling or 458 459 revegetation seed mixes can confound conclusions from these studies. The northern jarrah forest where our site is situated is characterised by an overstory dominated by 460 jarrah (E. marginata) and marri (Corymbia calophylla) tree species, and most of the 461 regions floristic diversity is found in the understory and groundcover (Koch & Samsa 462 2007). Seed mixes at our sites have changed over time, with over 200 species 463 464 directly seeded in the youngest sites compared to 40 species directly seeded in our oldest sites. While these changing practises introduce confounding factors into 465 chronosequence studies, the direct return of topsoil does also return the native 466 467 seedbank that will help reduce the impact of differences in species directly seeded. However, in contrast to soil bacterial community trajectories, vegetation communities 468 in recently restored sites more closely resemble reference sites than do older 469

470 restored sites (George et al 2009). The cause and consequences of this apparent
471 disassociation between above and below ground trajectories requires further
472 investigation.

473

In natural soil systems, succession in bacterial communities is thought to be initially 474 stochastic before becoming increasingly deterministic (Dini-Andreote et al. 2015), 475 476 where soil properties (particularly pH, availability of soil carbon, and nitrogen) and plant-soil feedbacks drive succession (Fierer 2017). Succession in soil bacterial 477 478 communities in human-altered systems, such as in response to rehabilitation 479 interventions following mining and agriculture, are less understood with only a handful of recent soil genomic studies showing patterns of compositional differences 480 481 in bacterial communities following rehabilitation (e.g. Barber et al. 2017; Gellie et al. 2017; Ngugi et al. 2018; Yan et al. 2018; Schmid et al. 2020; van der Heyde et al. 482 2020). None of these previous studies however address the degree of variation in 483 484 bacterial communities among reference sites, or how this potential variation can 485 impact what we determine to be an appropriate rehabilitation target to which we should be comparing rehabilitated sites against. 486

487

Our results clearly indicate bacterial community composition in older rehabilitated sites was as similar to community composition in reference sites as the communities in individual reference sites are to the other reference sites. This similarity however highlights the low degree of among-reference site similarity in bacterial communities and highlights the need for future studies to better consider this high degree of variation. Our reference-to-reference comparison showed a median similarity of 40% at the zOTU level. While this degree of similarity is influenced by the analysis

methods (i.e., ecological distance measures, sequence grouping or clustering
approaches, multiplexing, denoising), we do not aim to establish here if zOTU levels
of resolution provide the most appropriate indication of progress towards the
reference target. We conduct a comprehensive methodological investigation using
soil bacterial community data in chronosequence studies that explore these points in
detail in Liddicoat et al. (2022).

501

502 Here, we sampled six reference sites embedded within both the mine and our 503 rehabilitated sites to provide an indication of the variation present in the bacterial community among reference sites in general. This among-reference site variation 504 confirms expectations from known associations between soil bacterial communities 505 506 and soil physical and chemical characteristics, and how both these factors can vary 507 spatially (Green & Bohannan 2006; Neupane et al. 2019). Previous studies using a chronosequence design to explore changes in soil microbial communities following 508 509 mine site rehabilitation have only sampled limited numbers of reference sites (e.g., 1-510 3 sites) (Ngugi et al. 2018; Schmid et al. 2020; van der Heyde et al. 2020) and none 511 have reported on the variation present among reference sites. With spatial variation of bacterial communities being so scale dependant (Fierer 2017), the degree of 512 513 variation among reference sites will likely impact interpretations of communities 514 being used as the target. We recommend future studies that assess recovery 515 trajectories of soil microbiota with a chronosequence design capture spatial variation among reference sites by sampling many reference sites that geographically span 516 517 the study site. This reference site selection should be done to ensure an adequate representation of soil and vegetation community heterogeneity across the study site 518 519 and, where possible, pair rehabilitated sites with a nearby reference site to maximise

similarity between sites and therefore increase the chances of isolating the effect ofinterest.

522

523 While our study design included an even spatial distribution of our rehabilitation sites with reference sites throughout the mine area, we observed a significant positive 524 correlation between bacterial community dissimilarity and geographic distance. This 525 526 association was largely driven by three sample sites, and when these sites were 527 removed there was no longer a significant association, supporting our conclusion of 528 an effect of time, rather than space, on bacterial communities across the 529 chronosequence. This spatial effect on bacterial community composition is likely to be driven not only by our spatial outliers but also by associations between soil abiotic 530 531 properties (e.g., pH, potassium or other unsampled soil parameters) and microbial community composition (Martiny et al. 2011). As geographic distance between 532 samples increased, so do changes in soil properties. This environmentally driven 533 534 spatial variation of soil microbial communities highlights the need for appropriate 535 experimental designs that limit spatial confounders where practicable or address their ecological implications. Furthermore, to experimentally test cause-effect 536 relationships in a rehabilitation context, either experiments need to be embedded 537 538 into rehabilitation sites (Gellie et al. 2018) or longitudinal studies need to be done to 539 conclusively ascertain temporal changes in soil microbiota (Lem et al. 2022). Also, to 540 investigate any potential return of key bacterial-mediated ecological functions, future studies should incorporate shotgun metagenomic data to directly ascertain changes 541 542 in functional gene abundances as inferring any functional changes from 16S data 543 alone is problematic (Sun et al. 2020).

544

545 While we found no difference in bacterial alpha diversity across the chronosequence we do note this lack of difference may have been caused by our observed zOTU 546 547 richness not reaching the species asymptote in all samples. Previous studies have shown a variety of bacterial diversity changes with rehabilitation, including higher 548 diversity in younger sites before peaking in moderately aged sites and then diversity 549 reductions towards reference sites (Barber et al. 2017; Sun et al. 2017). These 550 551 previously published diversity patterns were explained as resulting from an initial 552 disturbance, followed by rapid expansion of generalist and opportunistic taxa, before 553 niche specific taxa begin to establish as the vegetation community re-establishes (Kardol & Wardle 2010; Liddicoat et al. 2019). However, these trends are by no 554 means universal, and similar to our results, other studies have shown no change or 555 556 significant differences in soil bacterial alpha diversity attributable to age across a chronosequence (Gellie et al. 2017; Yan et al. 2019; Schmid et al. 2020). These 557 discrepancies in the response of soil bacterial alpha diversity to rehabilitation makes 558 559 predicting a response of soil bacterial diversity a priori difficult. Soil microbial 560 diversity has been shown to have links to aboveground biodiversity and ecosystem services and functions (Fierer et al. 2012; Bardgett & Van Der Putten 2014; Prober 561 et al. 2015; Bender et al. 2016). However, higher diversity does not necessarily 562 563 reflect greater ecological integrity than lower diversity, and neither does it imply 564 greater or improved functionality (Shade 2017). To assess any change in bacterial 565 functions, future studies would benefit from incorporating assessments of functional gene abundances through time following restoration. The initial topsoil disturbance in 566 567 mining and any prolonged topsoil storage can negatively impact on soil microbial diversity, potentially reducing functionality. In this case however, the mine's direct 568

return approach has potentially limited the impact of degrading processes on soilmicrobiota reducing impacts on soil diversity.

571

572 In conclusion, by using high-throughput amplicon sequencing of the bacterial 16s rRNA gene, we show a clear recovery trajectory in soil bacterial communities 573 following post-mining rehabilitation as well as high variability among reference sites. 574 575 This among-reference variability highlights the need for restoration chronosequence 576 studies to sample several reference sites that geographically span the rehabilitation 577 site and/or are spatially paired with rehabilitated sites to improve inferences of a recovery trajectory. Our results provide further evidence of the association between 578 579 soil pH and bacterial community composition and suggest further research is needed 580 to determine if recovery timeframes can be improved by modifying soil pH early in 581 the rehabilitation process. Overall, our study provides a robust perspective of how environmental DNA can be used as a monitoring tool within an improved 582 583 chronosequence design to assess the recovery trajectory of degraded ecosystems 584 following restoration interventions.

Figure 1. Map of sampling sites from the rehabilitation chronosequence at South

- 846 32's Worsley bauxite mine in southwest Western Australia. Circles indicate sampling
- sites, with colour representing year of rehabilitation. Soil was sampled from two
- 848 depths (0-10 cm and 20-30 cm) at each site.

- significantly different to reference sites at the 0-10 cm depth and 2017, 2011, 2005,
- 1999, and 1996 are different to reference sites at the 20-30 cm depth).

871 community composition (Bray-Curtis dissimilarity) and associated soil chemical

variables at (A) 0-10 cm depth and (B) 20-30 cm depth. Blue arrows indicate

873 direction of influence of soil variable on bacterial communities.

Figure 5 Scatterplot of the association between the distance between samples
(Haversine distance matrix) and bacteria community composition (Bray-Curtis
distance matrix), showing Mantel test statistics. (A) shows a significant correlation
present with all sites included, and (B) shows no significant correlation with three
geographically separate sites removed indicating these three sites are driving the
spatial autocorrelation.
