#### **ABSTRACT**

Dermestes undulatus is a scarce species in the UK. Here we report on the rediscovery of D. undulatus from southern Wales, specifically the island of Flat Holm. The historic and current distribution of D. undulatus in the UK is explored. Dermestes undulatus sits within the subgenus Dermestinus, along with D. murinus. The differentiation of D. undulatus from D. murinus is considered.

Keywords: hide beetle, distribution, lardarius, United Kingdom, identification, recording

#### **INTRODUCTION**

Holloway (2023) examined the checklist of *Dermestes* Linnaeus, 1758 species on the British list, concluding that only six species should be included. Of these six species, three belong within the subgenus *Dermestes* (*D. lardarius* Linnaeus, 1758, *D. haemorrhoidalis* Küster, 1852, *D. peruvianus* Laporte de Castelnau, 1840) and three belong within the subgenus *Dermestinus* Zhantiev, 1967 (*D. maculatus* DeGeer, 1774, *D. murinus* Linnaeus, 1758, *D. undulatus* Brahm, 1790). Holloway (2023) used Duff's (2018) self-sustaining population criterion for inclusion onto the British list. This criterion could include species that breed largely indoors. Three of the species listed above have entered the UK probably many times on imported commodities and have subsequently established themselves indoors, meaning that only three species, *D. lardarius*, *D. murinus*, and *D. undulatus* are truly native.

Dermestes undulatus is globally a widely distributed species occurring throughout the entire Holarctic region (Mroczkowski 1968). In the UK, however, it is a scarce species that could be declining (Peacock 1993). It is listed as rare and vulnerable by Alexander (2017). Both D. undulatus and D. murinus belong to the same subgenus, Dermestinus, and are fairly similar to

each other. The purpose of the current study is to examine ways of differentiating between the two species for recording purposes, and to consider the distribution of *D. undulatus* in the UK.

#### **METHODS**

Adults were noted on Flat Holm, Wales (ST221649) by two of us (CO and GT) during a three-day Bioblitz (8<sup>th</sup> – 10<sup>th</sup> September 2023) on the island organized by Southeast Wales Biodiversity Records Centre in conjunction with Cardiff City Council and Flat Holm (Cardiff Harbour Authority and Flat Hom Island team). Six adults and a late-stage larva were sent to GJH to establish a breeding population and to confirm identification. Adult insects were provided with dry chicken flesh, feathers, and crushed whole cereal grain as a breeding medium.

Dissection was carried out under a Brunel BMSL zoom stereo LED microscope and involved detaching the abdomen from the rest of the insect using two entomological pins. The soft tergites were peeled away from the harder ventrites to expose the genitalia. Habitus and sternite images were captured at ×10 magnification using a Canon EOS 2000D camera mounted on the BMSL microscope. After dissection, all body parts were mounted on card. The antennae were teased out and images were taken at ×63 magnification. Images were fed through Helicon Focus Pro focus-stacking software (version 8.2.2).

Distribution data were lifted from iRecord (2024) and NBN Atlas (2024), supplemented with old data provided by Peacock (1993). The distribution map was produced using SimpleMappr (Shorthouse 2010).

#### RESULTS AND DISCUSSION

Several Coleoptera species were found associated with dead juvenile lesser black-backed gulls Larus fuscus Linnaeus, 1758 along with D. undulatus, including Aleochara bipustulata Linnaeus, 1761, Necrobia violacea Linnaeus, 1758, Nicrophorus humator Gleditsch, 1767, Nicrophorus vespillo Linnaeus, 1758, Omosita colon Linnaeus, 1758, Saprinus planiusculus Motschulsky, 1849, and Saprinus semistriatus Scriba, 1790. Dermestes undulatus was one of the most common Coleoptera species on site and up to about 50 were found on and under every gull carcass examined. Four adult females and two males D. undulatus were received by GJH on 16th September 2023 (the larva later developed into an adult male). The adults lived indoors for about 3 months but failed to produce any offspring. On death, the specimens were dissected to confirm identification as D. undulatus (Herrmann 2024) (Fig. 1). There could be different explanations for the unwillingness of the insects to breed under laboratory conditions. They are collected in September, which is late but within the normal period that adults are found in the field (March – September, Peacock (1993)). One explanation is that adults need an overwintering period to completely mature, a period that might need to include low temperatures. They were kept at a fairly steady 20°C so were never exposed to low temperatures. Another possibility is that they need their food to be damp. The food offered to them in the laboratory was dry, similar to food and conditions provided for laboratory cultures of *D. maculatus* and *D. ater* DeGeer, 1774.

The only confusion species likely to be encountered out of doors and which belongs to the subgenus *Dermestinus* is *D. murinus* (Fig 2). Both *D. undulatus* and *D. murinus* are about the same size with body lengths 5-8 mm. The dorsal colour patterns (Figs 1A and 2A) are the

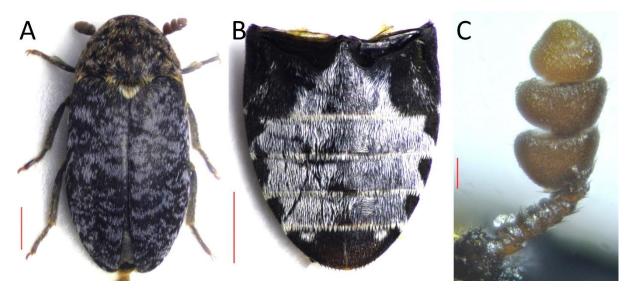

Fig. 1. *Dermestes undulatus* (Flat Holm, Wales, September 2023), A: Habitus (scale bar = 1 mm), B: sternites (scale bar = 1 mm), C: antenna (scale bar =  $100 \mu m$ ).

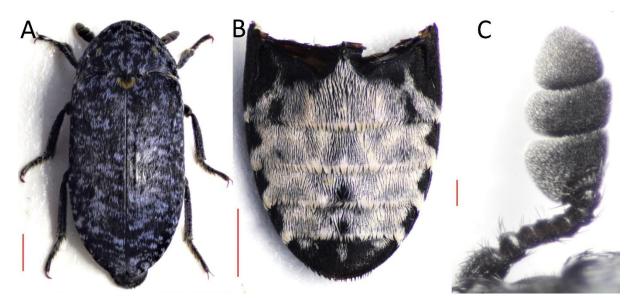

Fig. 2. *Dermestes murinus* (Silwood Park, April 2019), A: Habitus (scale bar = 1 mm), B: sternites (scale bar = 1 mm), C: antenna (scale bar =  $100 \mu m$ ).

same, flecks of white scales on an otherwise black background, except that *D. undulatus* also has brown scales on the pronotum and (sometimes) the elytral base. *Dermestinus* species have white scales on the sternites. The patterns of these white scales (Figs 1A and 2A) differ between the species. In particular, the large patches devoid of white scales at the outer edges of sternite I are typical of *D. undulatus*. Sternite I is more extensively covered in white scales in *D. murinus*. Both species have obviously clubbed antennae with the club consisting of the terminal three antennomeres. The structures of the clubs are similar, but *D. undulatus* club is pale reddish brown and *D. murinus* club is very dark brown or black.

Fig 3 shows a map of recent and old records of *D. undulatus* from the UK. Most records are from the coast and there is little difference between the types of locations and distributions

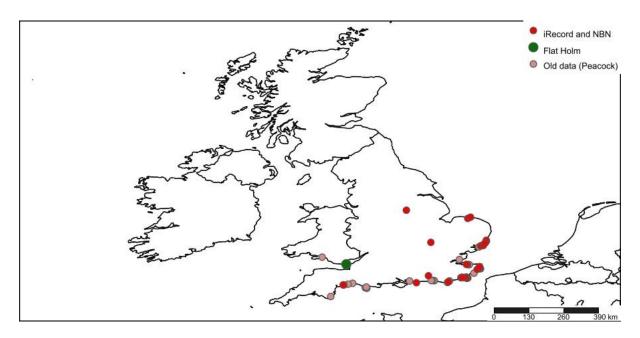

Fig. 3. Distribution of *Dermestes undulatus* in the UK, including Flat Holm, Wales record.

between old and new records. In short, there is little evidence that *D. undulatus* is becoming less frequent in the UK, although it should be noted that recording effort is probably higher now than in the past. Only three records occur away from coastal regions: Nottinghamshire, Bedfordshire and Sussex. It is possible that these records are geospatial errors or misidentifications, but either way they do not change the indication that in the UK *D. undulatus* is essentially a coastal species.

The Flat Holm record is indicated on Fig 3. Only twice before has *D. undulatus* been recorded in Wales, both times from Swansea. The first recording was from approximately 200 years ago, and thereafter approximately 100 years ago (Peacock 1993). Fig 3 shows that *D. undulatus* is distributed largely along the south and south-east coasts. The Flat Holm record is far removed from the distribution focus in the UK. It is possible that it is a relict population that has, to date, been overlooked, or it represents range expansion.

#### **ACKNOWLEDGEMENTS**

We are very grateful to Georgia Warren for making us aware of a record of *Dermestes undulatus* from a new site (Pagham Harbour, West Sussex) in July 2023.
