23 **Abstract**

24 The introducton of earthworms into soils contaminated with metals and metalloids has

25 been suggested to aid restoration practices. Epigeic, anecic and endogeic earthworms

26 were cultivated in soil with 1130, 345, 113 and 131 mg kg^{-1} of As, Cu, Pb and Zn

27 respectively for up to 112 days in parallel with earthworm-free controls. Different

28 ecological groups affected metals in the same way by increasing concentrations and

29 free ion activities in leachate, but anecic *Lumbricus terrestris* had the greatest effect

30 by increasing concentrations of As by 267%, Cu by 393%, Pb by 190%, and Zn by

31 429%. Ryegrass grown in earthworm-bearing soil accumulated more metal and the

32 soil microbial community exhibited greater stress. Results are consistent with

33 earthworm enhanced degradation of organic matter leading to release of organically

34 bound elements. The impact of earthworms on metal mobility and availability should

35 therefore be considered during risk assessment and when inoculating earthworms into

36 contaminated soils.

41 Earthworms increase the mobility and availability of As, Cu, Pb and Zn in a

42 contaminated soil.

43

Introduction

Earthworms often represent a significant proportion of the soil biomass and hence make an important contribution to the decomposition of organic matter, cycling of nutrients and pedogenesis. It has been estimated that earthworms in arable and grassland soils produce over 90 tonnes ha^{-1} of casts annually [1]. Earthworms can survive and reproduce in soil anthropogenically-contaminated with metals [2-4]. It is their importance in soil formation, functionality and ecosystem services that has led to the introduction of earthworms to physically degraded or chemically contaminated soils during remediation activities [5-7]. Earthworm inoculation has the potential to become a commonly used practice during remediation and ecological restoration and is therefore being investigated as such. However, generally earthworms increase the mobility and availability of metals [8]. This clearly has significant implications for their use in remediation. It has been suggested that the changes in mobility and availability are a direct consequence of a reduction in soil pH or an increase in dissolved organic carbon due to earthworm activity, leading to changes in elemental speciation [8]. Alternatively the changes may be due to alterations to the microbial population or the sequestration of metals into earthworm tissues and their subsequent excretion [8].

Earthworms can be classified into three ecological groups according to their life history strategies [9]. Epigeic earthworms, e.g. *Eisenia veneta* (Rosa), live in the litter layer above the mineral soil and feed on organic matter in the litter layer. Anecic earthworms, e.g. *Lumbricus terrestris* (L.), create permanent vertical burrows and feed predominantly on organic matter which they drag from the soil surface into their burrows. Endogeic species, e.g. *Allolobophora chlorotica* (Savigny), are

68 predominantly geophagous, form non-permanent horizontal burrows and feed on the

69 organic matter in the soil and the associated microbial biomass.

70

71 The aim of this study was to determine the impact that introduced earthworms from

72 these three different ecological groups have on metal and metalloid mobility and

73 availability in soils and the mechanisms for this. Therefore we introduced earthworms

74 into highly disturbed, unnatural conditions, such as they might experience if added to

75 soil under-going remediation. Mobility and availability of metals was assessed

76 through a combination of bioassays, pore water and leachate analysis, chemical

77 speciation modelling and phospholipid fatty acid profiling of the soil microbial

78 community.

79

80 **Experimental**

81 **Earthworms and Soil**

82 Earthworms were obtained from commercial sources or collected from the field.

83 *Lumbricus terrestris* (6.0 g, SD = 0.07, n = 24) were sourced from Worms Direct,

84 Ulting, UK., *Eisenia veneta* (1.2 g, SD = 0.03, n = 60) were sourced from Blades

85 Biological Ltd, Edenbridge, UK and *Allolobophora chlorotica* (170 mg, SD = 4.0, n =

86 240) were collected from the University of Reading farm at Sonning, Berkshire, UK.

87 on the Thames floodplain. All earthworms were kept in a moist Kettering loam and

88 Irish moss peat mixture (2:1 v/v) prior to use. They were fully clitellate (mature), and

89 responded to physical stimulus prior to addition into test media.

90

91 Soil was collected (0-30 cm) from a grassed field (SX 423 736 GB grid) identified as

92 a former settling pond for the separation of metal from crushed ores at Devon Great

93   Consols, an abandoned copper and arsenic mine near Gunnislake, UK [10]. The soil was

94   homogenised and sieved with a 6.7 mm sieve to remove large stones and roots before

95   addition to leaching columns.

96

97   Soil properties are shown in Table 1. Soil mineralogy was determined by X-ray

98   Diffraction Analysis (PANalytical X'Pert series) and a Rietveld refinement [11] and

99   comprised mostly quartz (38.4%) and mica (30.5%) with trace amounts of chlorite

100   (7.0%), K-feldspar (4.4%), kaolinite (4.3%) and albite (3.0%). There was a significant

101   quantity of amorphous material (12.4%) likely to be mostly iron oxyhydroxides and

102   organic matter.

103

104   **Experimental design**

105   Forty eight leaching columns (300 mm height, 110 mm diameter) were filled with

106   900 g (dry wt.) of soil moistened to 80% of the water holding capacity (65% moisture

107   content). Two *L. terrestris*, five *E. veneta* or 20 *A. chlorotica* were added to 12

108   columns, see Table SI-1 for masses. Twelve control columns were earthworm free.

109   Columns were maintained at constant soil moisture, arranged randomly in a constant

110   temperature room at 18 ºC in a 12 hour light-dark cycle. Earthworms were not fed

111   during the test duration so that any effects observed were due to the activities of the

112   earthworms and not the incorporation of organic matter. The top of the columns were

113   covered and secured with net curtain to unsure the earthworms did not escape. A

114   rhizon sampler was inserted 130 mm below the soil surface on day 1 and used to

115   sample soil pore water in each column after 12, 36, 64 and 92 days. On each occasion

116   the suction was appled for 16 hours. Four columns per treatment were destructively

117   sampled after 28, 56 and 112 days.

118

119   Three days before the destructive sampling of a column (days 25, 53 and 109), 296 ml

120   of ultra pure (>15 MΩ) water was poured onto the surface in order to saturate the soil

121   and generate downflow of soil solution through the column; leachate was collected.

122   Pore water and leachate were filtered to <45 μm (Whatman Cellulose nitrate

123   membrane filters) and analysed for As, Cu, Pb and Zn using an ICP-OES (Perkin

124   Elmer Optima 3000 Inductively Coupled Plasma-Optical Emission Spectrometer). As

125   and Pb were below detection limits (26 and 8 μg L^{-1} respectively). Therefore, leachate

126   samples from columns destructively sampled after 112 days were analysed for As and

127   Pb with an ICP-MS (Agilent Technologies 7500 Series Inductively Coupled Plasma

128   Mass Spectrometer). Pore water and leachate samples were analysed for major anions

129   (Dionex DX-500 ion chromatograph), pH, Eh and Total Organic Carbon (TOC)

130   (Shimadzu TOC 5000).

131

132   Twenty eight days before a column was due to be destructively sampled (i.e. day 1, 28

133   and 84), it was seeded with 0.37 g of perennial ryegrass (*Lolium perenne* L.). Twenty

134   one days after sowing, the grass was harvested, dried, weighed and the shoots

135   digested in nitric acid [12] to determine Cu and Zn (ICP-OES) and As and Pb (ICP-MS)

136   concentrations.

137

138   Earthworms recovered from destructively sampled columns were depurated for 48

139   hours [13]. Depurate collected after 112 days exposure was frozen along with one

140   sample of bulk soil per treatment for the determination of As speciation in the soil by

141   X-ray Absorption Spectroscopy (XAS). Depurated earthworms were frozen before

142   digestion in nitric acid [14]. Their metal and metalloid loadings were determined by

7

ICP-OES. Soil from the columns was air dried, sieved to 2 mm and pH (BS7755-3.2

[15]) and water soluble carbon (WSC) [16] determined. The microbial community

structure and biomass were assessed using phospholipid fatty acid (PLFA) profiles on

frozen samples of the 112 day incubated soil.

Speciation modelling

Speciation of Cu, Pb and Zn in porewater and leachate samples was modelled using

WHAM VI [17]. In the absence of characterisation of the TOC fractions, we assumed

that 50% of TOC was fulvic in origin and that the fulvic acid contained 50% C [18]. The

speciation of As was modelled with PHREEQCi [19] using the WATEQ4F database [20].

X-ray Absorption Spectroscopy (XAS) experiment

Station 16.5 at SRS Daresbury Laboratory, Warrington, UK was used to obtain As

K-edge spectra of earthworm depurate to compare with bulk earthworm-worked soil

and earthworm-free control soil. Frozen soil was ground with a pestle and mortar and

mounted in an aluminium planchette for exposure to the X-ray beam at liquid nitrogen

temperatures. Spectra of the control soil sample, samples of soil worked by each of

the earthworm species and the depurate of each of the earthworm species were

collected and analysed following the method of Arnold *et al.* [21].

Phospholipid Fatty Acid (PLFA) analysis

Soils were extracted using Bligh and Dyer solvent [22] according to Frostegård and

Bååth [23]. Extracted phospholipids were derivatized according to Dowling *et al.* [24] and

analysed as fatty acid methyl esters by gas chromatography (Agilent 6890N, flame

ionization detector and a 30 m x 0.25 mm capillary column with a 0.25 μm film of 5%

168   diphenyl, 95% dimethyl siloxane) according to Frostegård *et al.* [25] alongside a 200 µL

169   C19:0 internal standard. The initial oven temperature was set at 60 ºC and raised to

170   145 ºC at 25 ºC min.$^{-1}$ and then to 250 ºC at 2.5 ºC min.$^{-1}$ and finally at 10 ºC min.$^{-1}$ to

171   310 ºC where it was held for 10 minutes. Individual fatty acid methyl esters were

172   identified and quantified according to the retention times and peak areas in qualitative

173   (26 bacterial FAMEs, C11 to C20; Supelco, Supelco UK, Poole, UK) and quantitative

174   (37 FAMEs, C4 to C24; Supelco, Supelco UK, Poole, UK) standards. Individual

175   PLFAs were attributed to various microbial groups according to Zelles [26], Frostegård

176   and Bååth [23] and Kaur *et al.* [27]. Fatty acid nomenclature follows Frostegård *et al.* [28].

177

178   **Statistical analysis and quality control**

179   Genstat version 9 was used for all statistical analysis. One-way analysis of variance

180   (ANOVA) and Fisher's Least Significant Difference test were used to test significant

181   differences between treatments. Normality was confirmed by inspecting the residual

182   plots. Principal components analysis (PCA) was carried out on normalised PLFA data

183   using the variance-covariance matrix.

184

185   Pseudo-total elements determined by digestion of soil in aqua regia was run alongside

186   an in-house reference material traceable to BCR-143R - trace elements in a sewage

187   sludge amended soil (Commission of the European Communities, Community Bureau

188   of Reference) certified for Pb and Zn and with an indicative value for Cu. Recoveries

189   were 90%, 99% and 91% for Cu, Pb and Zn respectively. Digestion of plant material

190   in nitric acid was run alongside an in-house plant reference material traceable to CRM

191   GBW 07603 - bush branches and leaves, (approved by State Bureau of Technical

192   Supervision, The People's Republic of China, Institute of Geophysical and

193   Geochemical Exploration, Langfang, China) certified for As, Cu, Pb, and Zn.

194   Recoveries were 94%, 106% and 89% for Cu, Pb and Zn respectively. As was below

195   the limit of detection in the in-house reference plant material (6.3 mg kg^{-1}). The

196   digestion of earthworm tissue in nitric acid was run alongside ERM CE278 – mussel

197   tissue (European Commission, Institute for Reference Materials and Measurements)

198   certified for As, Cu, Pb and Zn. Recoveries were 113%and 93% for Cu and Zn

199   respectively. As and Pb were below the limit of detection in the mussel tissue (9.1

200   mgAs kg^{-1} and 3.5 mgPb kg^{-1}).

201

Results and discussion

203   Mortality data and the concentrations of As, Cu, Pb and Zn in earthworm tissue are

204   presented in Table SI-2. *A. chlorotica* showed the greatest mortality but there was no

205   increase in mortality over time. All the *L. terrestris* and *E. veneta* survived in the 24

206   and 56 days treatments, but some mortality did occur in the 112 days treatment.

207   Earthworm metal body burden increased significantly ($p<0.05$) with time for Cu, Pb

208   and Zn (*A. chlorotica*), Pb and Zn (*L. terrestris*) and Pb (*E. veneta*).

209

Impact of earthworms on metal and metalloid mobility

211   Metals and metalloids in solution will be mobile in soils through diffusion and

212   advection. In all treatments, including the earthworm-free controls, the concentration

213   of Cu and Zn in pore water increased significantly ($p<0.01$) with time (Table 2).

214   However, the concentration of both Cu and Zn in pore water after 36, 64 and 92 days

215   was significantly greater ($p<0.05$) in the columns containing *L. terrestris* or *E. veneta*

216   compared with the control columns. This observation indicates that the mechanism(s)

217   by which the earthworms increase metal and metalloid mobility may be a process

218 already occurring in earthworm-free soils that is being accelerated by the presence of

219 the earthworms. By day 111 the As, Cu, Pb and Zn concentrations were significantly

220 (p<0.01) greater in the leachate from columns inhabited by *L. terrestris* compared

221 with the control columns (Table 3 and 4).

222

223 These results are consistent with others in the literature [29-31] in which earthworm

224 activity in soils increased the concentration of water soluble metals. Although fewer

225 individuals of *L. terrestris* (2) were added to each column than for either *E. veneta* (5)

226 or *A. chlorotica* (20), the ratio of earthworm biomass to soil mass was in the order *L.*

227 *terrestris > E. veneta > A. chlorotica* (Table SI-1) and this probably accounts for *L.*

228 *terrestris* having the greatest effect on the metal and metalloid mobility in soil.

229

230 **Impact of earthworms on metal and metalloid speciation**

231 The bioavailability of metals and metalloids is controlled not just by the presence of

232 elements in solution but by their speciation [32-34]. Our modelling indicates that free

233 ions and fulvic acid complexes made up over 99% of the modelled Cu, Pb and Zn

234 species in all pore water and leachate treatments in these experiments. The decrease in

235 pore water and leachate pH and DOC with time (Tables 2 and 3) led to a modelled

236 increase in the abundance of Cu and Zn free ions in solution and a concurrent

237 decrease in Cu and Zn-fulvic acid complexes (Table 2 and 3). Free ions of Cu and Zn

238 (and Pb in leachate) were most abundant in the pore water (Table 2) and 112 day

239 leachate (Table 3) from the *L. terrestris* and *E. veneta* inhabited columns compared

240 with the control columns. This indicates that the *L. terrestris* and *E. veneta* were not

241 only capable of increasing the mobility of Cu and Zn but also increasing the

242 proportion that is in a more available form.

243

244   The vast majority (>99.99%) of the As in the leachate was modelled as As(V). The

245   leachate from earthworm inhabited columns had a significantly (p<0.05) lower pH

246   (Table 3) compared with control columns. This resulted in a modelled relative

247   decrease in the abundance of the negatively charged $H_2AsO_4^-$ ion and an increase in

248   the uncharged H_3AsO_4 species. We did not have the binding constants to allow us to

249   model arsenic organic complexes in PHREEQCi. The modelled dominance of As(V)

250   in the water soluble As is based on measured platinium electrode redox potentials.

251   However, it may be that the AsIII/V couple is not in thermodynamic equilibrium [35]. It

252   is possible that As(III) may form in the anoxic conditions within the earthworm gut [36]

253   in response to thermodynamic drivers. This may be catalysed by associated or

254   ingested dissimilatory arsenate-reducing prokaryotes [37] and be present, in a

255   disequilibrium state, in the leachate. Reduction of As(V) to As(III) would contribute

256   to the observed increase in As concentration in the leachate from soils containing *L.*

257   *terrestris*, (Table 4), due to the higher solubility of As(III).

258

259   **Impact of earthworms on metal and metalloid availability to ryegrass**

260   Concentrations of As, Cu and Pb were significantly (p<0.05) greater in the shoots of

261   ryegrass grown on columns inoculated with *L. terrestris* compared with the

262   earthworm free control soil (Figure 1). In addition, the dry mass of the plant shoots

263   was not significantly (p>0.05) different between treatments after 56 and 112 days of

264   earthworm incubation (Table SI-3). Thus a greater mass of metals was extracted by

265   the ryegrass from the *L. terrestris* columns. This indicates that *L. terrestris* increased

266   the availability of these elements to ryegrass in agreement with a number of studies [30,

267   [38, 39]. However, *E. veneta* and *A. chlorotica* did not significantly affect the metal or

268 metalloid concentrations of the shoots of ryegrass (Figure 1). This is probably because

269 these species do not produce casts on the surface as anecic earthworms do. *L.*

270 *terrestris* deposits the soil that has passed through its gut on the soil surface at the top

271 of the column and this is what the ryegrass grew in.

272

273 **Impact of earthworms on soil properties**

274 Increases in metal mobility as a consequence of earthworm activity have been

275 explained as being due to either reductions in pH leading to displacement of metals

276 from binding sites on the soil surfaces [39], or the formation of organo-metal complexes

277 bringing metals into solution [40]. Our observation that earthworm activity decreased

278 soil pH and water soluble carbon (Table 5) is consistent with the hypothesis that

279 earthworm activity mobilised Cu, Pb and Zn due to a decrease in pH but not due to

280 the formation of organo-metal complexes. The decreases in pH do not however

281 explain the increases in As mobility because the increasing positive surface charge of

282 the oxides with decreasing pH would facilitate the sorption of arsenate oxyanions.

283 However, the observed increases in As mobility can be explained by reduction of

284 As(V) to As(III) in the anoxic earthworm gut.

285

286 The mechanisms by which earthworm activity increases the mobility and availability

287 of metals are unknown [8]. One possibility is earthworm facilitated decomposition

288 whereby organic matter is physically and chemically conditioned for microbial and

289 enzymatic attack [41]. The resultant release of organically bound metals and metalloids

290 would account for the increases in the mobility of elements in all the treatments,

291 including the control over time and the greater increase in the earthworm-treatments.

292 Decreases in soil pH (Table 5) may be due to earthworm-enhanced degradation of

293 organic matter leading to the release of organic acids [42]. Organic matter degradation

294 by indigenous microorganisms in the control treatments would explain the

295 significantly (p<0.01) lower soil pH in the control columns after 112 days compared

296 to 24 days (Table 5).

297

298 **Impact of earthworms on arsenic speciation**

299 The XANES spectra of all six earthworm-treated samples (faeces and bulk earthworm

300 worked soil) look the same as the spectrum of the control soil sample, with an edge

301 position characteristic of oxygen-bound As(V) (Figure SI 1). This similarity to the

302 control sample indicates that no difference in the speciation of the arsenic in the soil

303 between the treatments was detectable. The Fourier transform of each spectrum

304 exhibited a large peak at ca. 1.7 Å. The EXAFS was best fitted by 4 oxygens at 1.68-

305 1.69 Å (Table SI 4). Including As-O-O-As multiple scattering from the arsenate

306 tetrahedron [43] improved the residuals and part-filled (at low r) the second peak in the

307 Fourier transforms at ca. 2.8 Å. Further improvements to the fits could be made by

308 including a shell of phosphorus (or sulphur) scatterers at ca. 3.1 Å. Using heavier (e.g.

309 Fe) or lighter (e.g. O) scatterers instead of P or S also improved the residual, but to a

310 lesser degree. All seven EXAFS fits (one control soil, earthworm faeces for all three

311 species and bulk earthworm-worked soil for all three species) were essentially the

312 same (Figure SI 2) indicating that there is no evidence that the earthworms excreted

313 As into the soil in a structure different from that present in the earthworm-free control

314 soil.

315

316 There is evidence that earthworms sequester metals and metalloids within their

317 chloragogenous tissues in two distinct structures (O-donating, phosphate-rich granules

318   and S-donating ligands) and then subsequently excrete them in a form different from

319   that ingested [8, 44-47]. It is not known whether these structures persist in the

320   environment after excretion and if they significantly impact on mobility and

321   availability. However, in the current study, there was no difference in As speciation

322   between earthworm casts, earthworm-worked soil and control soil detectable by

323   XAFS. This may be because the proportion of the As in the soil that was affected was

324   small compared with the bulk of the As and any changes in As speciation were below

325   the limits of detection using this technique. None-the-less, despite evidence that As

326   speciation is altered within earthworms as a detoxification mechanism [48-50] we have

327   not been able to detect evidence for the persistence of these changes in the earthworm

328   worked soil.

329

330   **Impact of earthworms on soil microbial community composition**

331   There were distinct differences in the PLFA profiles for the different earthworm

332   species, as revealed by PCA. The first two components explained 58.3% and 16.5%,

333   respectively, of the variation in the data set, with the second principal component

334   separated the data according to the four earthworm treatments (Figure 2). The two

335   fatty acids with greatest influence on PC2 were 18:1ω9c (negative loadings) and

336   cy19:0 (positive loadings). The ratios of cyclopropyl fatty acids to their precursor *cis*

337   monounsaturated fatty acids are considered to be effective indicators of stress in soil

338   microbial communities [27, 51]. Therefore Figure 2 represents a separation of the

339   treatments in terms of the degree to which the microbial community is stressed.

340   Similar differences can be identified between the treatments when stress indicators

341   (ratios of the 18:1ω9t to 18:1ω9c and cy19:0 to 18:1ω9c fatty acids) are expressed on

342   a biomass basis (Table 6). *L. terrestris* and *E. veneta* significantly (p<0.05) increased

343   these ratios and the patterns of this stress are closely correlated to the degree to which

344   earthworms mobilise metals and metalloids.

345

346   The soils inhabited by all three species of earthworm have a lower microbial biomass

347   than the earthworm-free control soil and this is a significant difference ($p<0.05$) for

348   the soil inhabited by *A. chlorotica* (Table 6). This is evidence that different species of

349   earthworm impact the microbial community differently. Wen *et al.* [30] showed

350   increases in the microbial populations (measured by the cultivation-based dilution

351   plate method) of soils in which *Eisenia fetida* increased the mobility and

352   bioavailability of metals. However, no relationship between the size (biomass) of the

353   microbial community and the mobility or availability of metals or metalloids in the

354   soil was found in the current study. It therefore seems likely that mobilisation of

355   metals and metalloids by *L. terrestris* and *E. veneta* resulted in a toxicity-related

356   change in microbial community structure rather than the earthworms altering the

357   microbial community which in turn mobilised the elements. It can therefore be

358   concluded that increased metal availability due to earthworm activity changed the

359   microbial community to a more stressed state. It is unlikely that the presence of dead

360   earthworms in the soil had any affect on the PLFA profiles as this would have only

361   resulted in large error bars because the *L. terrestris* and *E. Veneta* treatments involved

362   replicate samples with both 50% and 0% mortality.

363

364   **Conclusion**

365   Our data support the hypothesis that earthworms stimulate the degradation of organic

366   matter and release organically bound metals and metalloids into solution. The

367   degradation of organic matter also releases organic acids which decrease the soil pH.

368 The earthworms do not appear to carry out a unique process, but increase the rate of a

369 process that is already occurring. Thus, earthworms would decrease the efficiency of

370 remediation when amendments are incorporated into soil to bind and immobilize

371 metals and metalloids. The impact of earthworms on the mobility and availability of

372 metals and metalloids should therefore be further quantified and considered during the

373 risk assessment of contaminated soils or when introducing earthworms into

374 contaminated soil as part of a land remediation scheme.

Table 2 Total Cu and Zn concentrations and the relative contributions of free ionic and fulvic acid-complexed (FA) forms, pH, and dissolved organic carbon (DOC) in pore water from control earthworm-free soil or soil inhabited by earthworms. Values are means of 12 replicates (12 and 36 days), 8 replicates (64 days) and 4 replicates (92 days) $\pm$SE. Asterisks indicate statistically significant differences between control and earthworm inhabited soils for the same sampling times at the 95% (*) and 99% (**) levels respectively. The percentage abundance of the free ion and fulvic acid complexes in solution was modelled on the mean of 12, 8 or 4 replicates using WHAM VI [17].
