Abstract

We report on the formation of hydrogel monoliths formed by functionalized peptide Fmoc-RGD [Fmoc: fluorenylmethoxycarbonyl] containing the RGD cell adhesion tripeptide motif. The monolith is stable in water for nearly 40 days. The gel monoliths have a self-supporting porous structure consisting of a network of peptide fibers. The RGD-decorated peptide fibers have a β -sheet secondary structure. We prove that Fmoc-RGD monoliths can be used to release and encapsulate material, including model hydrophilic dyes and drug compounds. We give a first insight into the correlation between absorption and release kinetics of this new material, and show that both processes take place over similar time scales.

Introduction

There is currently intense interest in the development of peptide-based hydrogels for applications in regenerative medicine/tissue engineering¹⁻¹² and the release of drugs and other actives.¹³⁻¹⁸ The peptide hydrogel as a minimum requirement must be cytocompatible, although many other elements are required to fully realise an artificial extracellular matrix (ECM).^{7,19} A common motif incorporated into peptide-based hydrogels is the Arg-Gly-Asp (RGD) tripeptide cell adhesion motif from fibronectin, which binds to integrins (cell-surface receptors) and is widely used to encourage cell growth in synthetic biomaterials.²⁰⁻²⁵ Here, we report on an RGD-based peptide hydrogel that can be used for slow release of hydrophilic compounds, illustrated with a model amyloid-binding dye and model hydrophilic dyes and drug compounds. The slow release concept could potentially be extended to other encapsulated hydrophilic molecules for use in slow release delivery systems or re-engineering of ECM mimics.

Previous works in the literature explored the gelation of fluorenylmethoxycarbonyl (Fmoc)-RGD. The first attempt on this subject was undertaken by Gazit and co-workers,²⁶ who initially dissolved Fmoc-RGD in dimethyl sulfoxide and then diluted in water to the final concentration, only achieving a clear solution. Shortly afterwards, Ulijn and co-workers have shown that Fmoc RGD can form a transparent hydrogel at low pH and peptide concentration.⁵

In a previous work²⁴ we reported on preparation of Fmoc-RGD peptide hydrogels for cell culturing. The Fmoc unit was used to control self-assembly in water, via aromatic stacking interactions. It was found that Fmoc-RGD forms well defined amyloid fibrils with a β -sheet structure for 2 wt% peptide. In addition, 2 wt% Fmoc-RGD forms self-supporting hydrogels.

Here, we investigate the formation of hydrogels in more concentrated solutions of Fmoc-RGD. This study is driven by the unusual mechanical properties of the 10 wt% peptide gel. We found that it is possible to make monoliths of 10 wt% Fmoc-

RGD hydrogel, which are stable when immersed in water for at least ~ 40 days. This property could find applications in the slow release of encapsulated materials. The structure of 10 wt% Fmoc-RGD hydrogel is examined by X-ray diffraction (XRD), small angle scattering (SAXS), cryo-scanning electron microscopy (cryo-SEM) and laser scanning confocal microscopy (LSCM). We investigate the uptake and release properties of Fmoc-RGD monoliths through fluorescence spectroscopy and UV-vis absorption experiments.

Experimental Section

Materials. Fmoc-RGD was purchased from CS Bio (Menlo Park, CA) as a TFA salt. Purity is 98.89% based on HPLC using TFA in water/acetonitrile gradient, M_w expected 568.59, found 568.87. Thioflavin T (ThT), methylene blue, salicylic acid and riboflavin were purchased from Sigma Aldrich (UK).

Hydrogel Formation. Weighed amounts of Fmoc-RGD and water were added in a vial to obtain a 10 wt% peptide suspension. The pH of the water used in this work was pH 6.94. 10 wt% Fmoc-RGD monoliths were obtained according to the two following alternative procedures:

i) The mixture was ultrasonicated for 15 minutes at 50 °C. The solution was stored at 5 °C for 15 hrs, and then placed again in an ultrasonic bath at 50 °C for 10 minutes. The cooling-heating/ultrasound process was repeated for 5 days, until the sample became a homogeneous gel.

ii) The mixture was ultrasonicated for 15 minutes at 50 °C. The solution was stored at 5 °C for 15 hrs. Then, the initial clustering of peptide was fragmented with a sterile needle and mixed with the excess of water in the sample using a magnetic stirrer. The mixture was finally allowed to gel at 5 °C for 2 days, in order to achieve homogeneity.

Congo Red Staining and Birefringence Monitored by Polarized Optical Microscopy (POM). A 0.5 wt% Congo red solution was filtered and then pipetted

onto a glass microscope slide. The peptide gel was placed under the surface of the Congo red solution and stained for approximately 2 min. The excess Congo red solution was then removed by blotting. Images of the sample placed between crossed polarisers were obtained with an Olympus CX-41 microscope.

Cryo-Scanning Electron Microscopy (cryo-SEM). Imaging was performed using an FEI Quanta 600F instrument. The peptide gel was mounted onto aluminium stubs and frozen in liquid nitrogen slush at approximately -210°C. Once frozen, the sample was transferred under vacuum to a sample preparation chamber and allowed to equilibrate to the appropriate temperature prior to fracturing. The gel was fractured at -140 °C and allowed to sublime at -90 °C for approximately 5 minutes before an initial examination by SEM. Following this a further 5 minutes of sublimation was used to reveal more detail of the sample surface. The sample was allowed to cool at -140 °C, and then coated with platinum prior to the final imaging at 5 kV.

X-ray Diffraction (XRD). A stalk, dried from a 10 wt% Fmoc-RGD gel, was prepared for XRD experiments. The stalk was mounted vertically onto the four axis goniometer of a RAXIS IV++ X-ray diffractometer (Rigaku) equipped with a rotating anode generator. The XRD data was collected using a Saturn 992 CCD camera.

Small-Angle X-ray Scattering (SAXS). SAXS was performed using a Bruker Nanostar instrument using CuK_α radiation from an Incoatec microfocus source. The sample was sandwiched between two mica windows with a 1 mm thick Teflon spacer. The sample-detector distance was 65 cm and a Vantec-2000 photon counting detector was used to collect SAXS patterns.

Laser Scanning Confocal Microscopy (LCSM). Experiments were performed using a Leica TCS SP2 confocal system mounted on a Leica DM-IRE2 upright microscope, using an objective x63 in a glycerol-immersion lens. A 10 wt% Fmoc-RGD gel was dyed using a 3.4×10^{-3} wt% ThT solution, instead of pure water, as a solvent. The sample was studied using 458 nm excitation wavelength (Argon laser emission), together with a 463-568 nm emission detection range.

Fluorescence Spectroscopy. Spectra were recorded on a Varian Cary Eclipse Fluorescence Spectrometer with samples in 10 mm quartz cuvette. ThT emission fluorescence was measured for $\lambda = (460-650)$ nm using $\lambda_{\text{ex}} = 440$ nm, while the fluorenyl emission fluorescence was measured for $\lambda = (290-470)$ nm using $\lambda_{\text{ex}} = 265$ nm.

UV-vis Absorption. Spectra were recorded using a Varian Cary 300 Bio UV/Vis spectrometer. Samples were analyzed in quartz cuvettes with a 5.0 mm path length and were baseline corrected with respect to a blank cell with the appropriate solvent.

Release of Fmoc-RGD monolith studied by ThT fluorescence. A quantity of 0.1 ml of 10 wt% Fmoc-RGD hydrogel was loaded with ThT by using 9.8×10^{-3} wt% ThT as a solvent. The monolith was then immersed in 1.5 ml of water. The fluorescence emission of the liquid surrounding the peptide monolith was measured as a function of time ($\lambda_{\text{ex}} = 440$ nm).

Release of Fmoc-peptide monomers from peptide monoliths studied by fluorescence. 0.1 ml of 10 wt% Fmoc-RGD monolith was prepared using water as a solvent, and then immersed in 1.5 ml of water. The fluorescence emission of small fractions of liquid surrounding the peptide monolith (0.01 ml diluted by 325-fold in water) was measured at regular intervals of time ($\lambda_{\text{ex}} = 265$ nm).

Release and uptake of methylene blue by Fmoc-RGD monoliths studied by UV-vis spectroscopy. Fmoc-RGD gel dye uptake was measured by immersing 0.1 ml of 10 wt% Fmoc-RGD hydrogel into 3 ml of 4.9×10^{-4} wt% methylene blue. In order to measure the release of dye by the hydrogel, we prepared 0.1 ml of 10 wt% Fmoc-RGD hydrogel loaded with methylene blue by using a 5.6×10^{-3} wt% methylene blue solution as a solvent. The hydrogel was then immersed in 3 ml of water. The UV-vis spectra of the solution surrounding the hydrogel were measured at regular interval of times, in order to evaluate both uptake and release of methylene blue by Fmoc-RGD monoliths.

Results and Discussion

Weighed quantities of Fmoc-RGD and water were mixed, inside a 0.5 ml Eppendorf, to a 10 wt% peptide concentration. The resulting gel surprisingly adopted a rigid structure, moulded by the Eppendorf tube, allowing for the preparation of a gel monolith similar to that displayed in Figure 1a.

The birefringence of the sample was studied by polarized optical microscopy and Congo red staining experiments. The latter assay is used to identify amyloid self-assembly, since uptake of Congo red leads to characteristic birefringence.²⁷ The texture obtained for the gel (Figure S1, Supplementary Information) suggests the formation of amyloid fibrils. This result was confirmed by the blue-green birefringence resulting from Congo red staining, shown in the inset of Figure S1.

Small angle X-ray scattering (SAXS) experiments were used as an *in situ* method to examine the self-assembled nanoscale structure. The SAXS intensity $I(q)$ measured for 10 wt% Fmoc-RGD was fitted using Porod's approximation for a long infinite cylinder, with a Gaussian size distribution to account for the polydispersity in cylinder radius (Figure 2). The fitting of the SAXS data in Figure 2 is not highly accurate at low scattering angles because our model does not consider interactions between the peptide fibrils (present at high concentrations)²⁸ but only the shape of the peptide fibrils. However, the SAXS fitting in Figure 2 corresponds to a radius $R = (35 \pm 5)$ Å, in good agreement with the cylinder radius (40 ± 18) Å previously found by us for 2 wt% Fmoc-RGD.²⁴ The estimated extended peptide length of 17 Å ($[3 \times 3.5 + 6]$ Å = 16.5 Å where 3.5 Å is the repeat distance β -strand and 6 Å is the estimated size of the Fmoc unit), compared to the fibril radius provided by SAXS in Figure 2, suggests that each Fmoc-RGD fibril is up to 4 extended Fmoc-RGD molecules in width.

The SAXS fitting in Figure 2 corresponds to a cylinder 300 Å long, shorter than the 800 Å long peptide fibrils previously measured by us for 2 wt% Fmoc-RGD from

the modelling of the SAXS data.²⁴ The wide difference in peptide length between 2 and 10 wt% peptide, reflects partly the high polydispersity in that structural parameter and also the lack of sensitivity of the fit to this parameter in the limit that the length $L \gg R$.

Cryo-SEM was used to image the self-assembled structure of the 10 wt% Fmoc-RGD gel. A representative image is shown in Figure S2 (Supplementary Information). The gel structure consists of a network of fibres, assembled to form a porous structure with a highly polydisperse pore size of (247 ± 100) nm (Figure S2a). The fibres comprising the network are (61.5 ± 23.1) nm thick (Figure S2b). Some clustering of fibres was observed, which may be the origin of the cloudiness observed for the hydrogel (Figure 1a). It is highly probable that the fibres in Figure S2b correspond to bundles of the 35 Å radius fibrils revealed by SAXS.

XRD was performed on a 10 wt% Fmoc RGD gel and on a stalk dried from such a gel. The 2D spectra revealed a partial orientation of the crystallographic planes (Figure S3, Supplementary Information). The meridional reflection at 4.71 Å (Figure S3) corresponds to the in-plane spacing of a β -sheet.²⁷ The equatorial reflections measured for the stalk (Figure S3), are associated to the lateral ordering of β -sheet strands.²⁷

Fmoc-RGD monoliths have pH 2. Our results show that when 0.1 ml of 10 wt% Fmoc-RGD is immersed in 3 ml of water, the initial pH of the water (pH 6.94) decreases to 3.86 after one minute, and remains stable with an average value of (3.47 ± 0.14) for the next two days. As a consequence of the acidic properties of the gel and the solution surrounding it, Fmoc-RGD monoliths might find applications as topical agents for encapsulation of drugs used in skin therapeutics.

The properties of Fmoc-RGD hydrogel as a slow release encapsulating agent were investigated. In particular, we qualitatively evaluated the interplay between the release and absorption properties of the hydrogel.

We prepared a 10 wt% Fmoc-RGD gel loaded with 3.4×10^{-3} wt% of the amyloid-binding fluorescent probe ThT. The resulting rectangular monolith is displayed in Figure 1b. The probe ThT was loaded to enhance visual observation and to allow for fluorescence experiments described below.

In order to study the release properties of the Fmoc-RGD hydrogel, a piece of the monolith in Figure 1b was immersed in water. The peptide gel initially remained stable in water (Figure 1c). By the ninth day it was possible to observe the detachment of a fibrillar structure, which continued to grow until the fortieth day (Figure 1d). Confocal microscopy was used to investigate the structure of the detached material in Figure 1d. The results, displayed in Figure 1e, show that peptide fibres detach, in a slow process, from the main body of the peptide gel. However, it is notable that after the detachment process, the initial aspect of the sample (Figure 1c) remained nearly unaltered after 40 days. It is remarkable that this gel, with no covalent cross-linking but only non-covalent supramolecular interactions, is so stable in dissolution.

The release kinetics from the concentrated Fmoc-RGD gel was studied by ThT fluorescence,²⁹⁻³⁰ following the procedure already described in the experimental section. The fluorescence emission of the solution fractions was characterized by a broad peak at 483 nm. The release curve, displaying the time-dependence of the fluorescence emission intensity at 483 nm, is shown in Figure 3.

It is well-known that ThT binds to amyloid peptide fibrils upon fibril self assembly, leading to an increase of ThT fluorescence emission at 480 nm ($\lambda_{\text{ex}} = 440$ nm).²⁹⁻³⁰ The release curve in Figure 3 shows that the fluorescence intensity increases with time, because the release process takes place through the detachment of β -sheet structures in the media, in agreement with the macroscopic detachment of fibres shown in Figure 1d. According to Figure 3, the release of

material becomes noticeable after 380 min. The release of amyloid fibrils from the hydrogel may be useful in creating novel functional amyloid-fibril materials.

We further studied the release of Fmoc-peptide monomers in the media using fluorescence spectroscopy, according to the procedure given in the experimental section. Previous studies on Fmoc-peptides solutions show that it is possible to monitor the emission of Fmoc-peptide monomers, by measuring the fluorenyl fluorescence at ~ 313 nm ($\lambda_{\text{ex}} = 265$ nm).³¹⁻³² In addition, the presence of fluorene excimers is detected by a red shift to 330 nm of the emission peak.³¹⁻³²

In our work, the fluorescence emission of the solution aliquots was characterized by peaks at 304 nm and 313 nm (Figure S4, Supplementary Information). We plotted the time dependence of the fluorescence emission at 313 nm, associated to peptide monomers,³¹⁻³² to construct the Fmoc-RGD monomer release curve shown in Figure 3. The time dependence of the fluorescence emission at 304 nm followed the same trend as that displayed for 313 nm (results not shown), suggesting that the fluorescence at 304 nm might also be associated with the Fmoc-unit.

The data in Figure 3 indicate that the release of Fmoc-RGD fibres is preceded by the expulsion of Fmoc-RGD monomers in the solution. Regarding drugs delivery applications, Figure 3 shows that the release of encapsulated material is ~ 380 min delayed with respect to the initial release of Fmoc-peptide monomers in the media.

The ThT fluorescence data in Figure 3 probes the release of material trapped in the fibres. The release and uptake of an alternative hydrophilic compound, which presumably is not hosted inside the peptide fibres but within the hydrogel pores, has also been examined. In particular, we performed UV/vis spectroscopy experiments to determine the uptake and release of methylene blue by Fmoc-RGD monoliths. Details of these experiments are given in the Experimental section. For Fmoc-RGD solutions, the maxima in adsorption bands are present between 233 and 309 nm (Figure S5, Supplementary Information) far removed from that of methylene blue

which exhibits $\lambda_{\text{max}} = 667$ nm, allowing simple determination of the dye taken up or released by the hydrogel.

Figure 4 displays the kinetics of the release and uptake experiments measured as the time dependence of the maximum in the adsorption band at 667 nm. Figure 4 shows that the release and uptake profiles of methylene blue by an Fmoc-RGD monolith develop over similar time scales, reaching a constant value 330 minutes after both processes have started.

Additional tests were performed in order to load the bioactive riboflavin and the hydrophilic pseudo-drug salicylic acid into Fmoc-RGD monoliths. In these experiments, the drugs were loaded by preparing gel monoliths using solutions containing the drugs as a solvent. The material loading capacity $\varepsilon = 100 \times \text{weight of material loaded} / (\text{weight of drug loaded} + \text{weight of dry Fmoc-RGD gel})$ is listed in Table 1, together with the data corresponding to the monoliths loaded with ThT and methylene blue used to perform release experiments shown in Figure 3 and Figure 4.

We further studied the absorbing properties of the Fmoc-RGD gel, following a qualitative visual method already used by Liebmann and co-workers to measure the mobility of dye throughout a Fmoc-dipeptide hydrogel.¹² We first prepared a gel loaded with 3.4×10^{-3} wt% ThT in an Eppendorf tube. Once the ThT-loaded gel was stabilized, an additional layer of 10 wt% Fmoc-RGD gel in pure water was formed on top, by hydrating freeze dried 10 wt% Fmoc-RGD gel. The additional peptide in water layer bound to the previously formed ThT-loaded hydrogel. One day after the ThT-free gel layer was stabilized, the two-layer hydrogel was removed from the Eppendorf mould. The resulting monolith is shown in Figure 5.

Figure 5 clearly shows a diffusion of dye from the ThT-loaded top towards the ThT-free base of the gel monolith. The shape of the monolith was maintained during the diffusion process, as a consequence of the rigid hydrogel structure. Since ThT is hosted within the core of the amyloid fibre, the diffusion within the gel points to the

porous structure displayed in Figure S2a, allowing local mobility of ThT molecules within the fibrillar network.

The results in Figure 1 and Figures 3-4, suggest that absorption and release processes might co-exist in a dynamic equilibrium in the Fmoc-RGD gel. It is possible that using Fmoc-RGD gel as a delivery agent *in vivo*, absorption of the physiological media will not screen the slow release of the encapsulated material.

Conclusions

In summary, this report shows that concentrated gels of Fmoc-RGD offer new opportunities for developing delivery agents. The unusual rigid structure of 10 wt% Fmoc-RGD gel allows for the construction of peptide-based monoliths able to remain stable in water for nearly 40 days, only partially affected by the detachment of peptide fibers. We found that the structure of Fmoc-RGD monoliths consists of a network of fibers, such that each fiber is made out of a bundle of thinner fibrils with an internal β -sheet structure. Fmoc-RGD fibres build a self-supporting but porous structure in a hydrogel functionalized with RGD motifs at high density.

The RGD sequence incorporated within the hydrogel provides biocompatibility via the integrin cell adhesion motif (it does not have a particular role in drug encapsulation) whereas the fibrillar structure of the monolith enables encapsulation and release. In particular, encapsulation can be achieved by loading the material in the gel (using a solution of the material as the solvent for Fmoc-RGD gel) or alternatively through the spontaneous uptake by the Fmoc-RGD gel of the material diluted in a surrounding liquid media.

Our findings represent a new approach to the use of the Fmoc-RGD peptide amphiphile as a delivery agent,³³⁻³⁴ and provide a first insight into a reliable correlation between absorption and slow release properties of this material.
