Final warming of the Southern Hemisphere polar vortex in high- and low-top CMIP5 models

L. J. Wilcox and A. J. Charlton-Perez

Department of Meteorology, University of Reading, Earley Gate, PO Box 243, Reading, RG6 6BB, UK

Abstract

The final warming date of the polar vortex is a key component of Southern Hemisphere stratospheric and tropospheric variability in spring and summer. We examine the effect of external forcings on Southern Hemisphere final warming date, and the sensitivity of any projected changes to model representation of the stratosphere. Final warming date is calculated using a temperature-based diagnostic for ensembles of high- and low-top CMIP5 models, under the CMIP5 historical, RCP4.5, and RCP8.5 forcing scenarios. The final warming date in the models is generally too late in comparison with those from reanalyses: around two weeks too late in the low-top ensemble, and around one week too late in the high-top ensemble. Ensemble Empirical Mode Decomposition (EEMD) is used to analyse past and future change in final warming date. Both the low- and high-top ensemble show characteristic behaviour expected in response to changes in greenhouse gas and stratospheric ozone concentrations. In both ensembles, under both scenarios, an increase in final warming date is seen between 1850 and 2100, with the latest dates occurring in the early twenty-first century, associated with the minimum in stratospheric ozone concentrations in this period. However, this response is more pronounced in the high-top ensemble. The high-top models show a delay in final warming date in RCP8.5 that is not produced by the low-top models, which are shown to be less responsive to greenhouse gas forcing. This suggests that it may be necessary to use stratosphere resolving models to accurately predict Southern Hemisphere surface climate change.

30 1 Introduction

The Southern Hemisphere (SH) stratosphere and troposphere have been shown to be coupled, with wave driving from the upward propagation of tropospheric Rossby waves influencing the stratospheric zonal wind, and anomalies in the stratospheric polar vortex having an impact down to the surface. This coupling predominantly occurs in the late spring, or summer, when the final warming of the polar vortex strongly influences both the stratospheric and tropospheric

circulation (Black et al., 2006), resulting in the stratospheric and tropospheric 37 annular mode having its largest variance in this season (Baldwin et al., 2003). 38 Changes in the strength of the polar vortex are associated with persistent circu-39 lation anomalies in the lower stratosphere, with weaker flow resulting in negative 40 Southern Annular Mode (SAM) anomalies. Thompson et al. (2005) showed that 41 final warming events are also associated with tropospheric circulation anomalies 42 of the same sign, which can persist for in excess of two months. They found that 43 significant increases in tropospheric geopotential height over the pole and de-44 creases in the midlatitudes, with a similar structure to the negative phase of the 45 SAM, followed major weakenings in the SH polar vortex. Coherent changes in 46 Antarctic surface temperature, with positive temperature anomalies over much 47 of the continent outside the Peninsula region, were also identified in association 48 with these changes. 49

Climate forcings have been shown to change the final warming date of the SH 50 polar vortex. In recent years, changes have been found to be strongly determined 51 by decreases in stratospheric ozone concentrations, with final warming dates 52 observed to be later in the 1990s compared to the 1980s (Waugh et al. (1999); 53 Zhou et al. (2000); Karpetchko et al. (2005); Langematz and Kunze (2006); 54 Haigh and Roscoe (2009)). Ozone depletion causes local cooling over the pole, 55 resulting in an increased temperature gradient and a stronger vortex, and hence, 56 later final warming dates. 57

Several studies have suggested that, in SH spring, the effects on surface 58 climate of ozone recovery and increasing greenhouse gases will be equal and 59 opposite, leading to a near cancellation, or even a reversal, in current trends in 60 the early twenty-first century (Arblaster et al. (2011); McLandress et al. (2011); 61 Polvani et al. (2011); Thompson et al. (2011); Wilcox et al. (2012)). Ozone 62 depletion causes a larger local decrease in temperature compared to greenhouse 63 gas increases, and has been shown to be the primary driver of recent changes 64 in final warming date (Langematz and Kunze, 2006). It is expected that ozone 65 recovery will similarly be the primary driver of near-term changes in final warm-66 ing date, and that the vortex breakdown will become earlier. A return to later 67 dates towards the end of the twenty-first century is possible as lower strato-68 spheric temperature trends become dominated by well-mixed greenhouse gas 69 forcing, which has been shown to result in an increased temperature gradient 70 near 100 hPa (Shindell et al. (1998); Wilcox et al. (2012)). If these changes are 71 coupled to the surface then changes in springtime Antarctic surface temperature 72 trends would be likely to occur in conjunction with these changes in the vor-73 tex. Therefore, one important facet of the stratospheric impact on tropospheric 74 climate is how external forcings may change the final warming date. 75

The significant tropospheric circulation anomalies associated with final warming events demonstrate that changes in the timing of this phenomenon will play a key role in future SH tropospheric circulation change (Black and McDaniel, 2007). Hence, understanding potential changes in final warming date, and their drivers, is an important part of SH climate prediction. Several studies have shown that the final warming signature in the SH propagates downwards (e.g. Baldwin et al. (2003); Thompson et al. (2005)). Hardiman et al. (2010) recently showed that this propagation begins at 1 hPa. As such, the representation of changes in final warming date may be sensitive to the position of the model top, which is often located near or below 1 hPa in models. Here, we attempt to quantify the effect of external forcings on SH final warming date, and the sensitivity of any projected changes to the position of the model top.

2 Data and Methods

The aim of this study is to identify robust changes in SH final warming date, 89 their drivers, and their potential sensitivity to the position of the model top. 90 The fifth Coupled Model Intercomparison Project (CMIP5) provides a unique 91 opportunity to analyse the response of a large number of models to the same 92 future greenhouse gas scenarios. CMIP5 also includes a substantial number of 93 'high-top' models, which have an explicit representation of the stratosphere. 94 High-top models have been defined here as those with model tops at pressures 95 ≤ 1 hPa, or altitudes ≥ 45 km. In addition to having a higher model top, the 96 high-top models used in this study typically have higher vertical resolution in 97 the stratosphere, and a larger proportion of model levels above 200 hPa (54%) 98 of high-top model levels are in the stratosphere, compared to 36% for low-99 top models). The models used in this study, their classification, and vertical 100 distribution of levels, are shown in Table 1. Only one model from each model 101 family is included in each classification to avoid biasing the ensemble mean. 102

We examine monthly mean data from the historical (1850-2005), Represen-103 tative Concentration Pathway (RCP) 4.5 (Thomson et al., 2011), and RCP8.5 104 (both 2006 to 2100) (Riahi et al., 2011) integrations. The two future pathways 105 result in a radiative forcing of 4.5 Wm^{-2} and 8.5 Wm^{-2} respectively by 2100, 106 with RCP4.5 carbon dioxide emissions peaking around 2040, and RCP8.5 emis-107 sions peaking in 2100. The rate of change of greenhouse gas concentrations 108 stabilises by ~ 2070 in RCP4.5, and continues to increase throughout RCP8.5 109 (Figure 1(a)). The time series analysed in this paper are concatenations of the 110 historical and RCP experiments for consistent ensemble members of each model, 111 and are referred to throughout by the name of the relevant future pathway. 112

Although a recommended ozone time series was compiled for CMIP5 (Cionni 113 et al., 2011), only three of the models used in this study are forced with these 114 data. Others included modified versions of the Cionni et al. (2011) data, some 115 prescribed ozone concentrations from different data sets, and others treat ozone 116 interactively. The different representation of ozone in the subset of CMIP5 117 models used in this study is shown in Table 1, following the categorisation of 118 Eyring et al. (2012). Example time series of the September to November mean 119 75°-90°S mean concentration at 50 hPa for each prescribed category are shown 120 in Figure 1(b), alongside the time series from models with interactive ozone. 121 Comparison of the different categories reveals a range of Antarctic stratospheric 122 ozone concentrations, with 1900 values between 2.4 ppmv and 4 ppmv. There is 123 some spread in the rate of recovery in the twenty-first century. Ozone concen-124 trations tend to recover faster in the time series from models with interactive 125

ozone. The relative change in ozone concentrations prior to 2000 is similar in the 126 interactive and Cionni timeseries, but smaller in the other prescribed categories. 127 However, the turning points are comparable across the categories (Figure 1(b)). 128 The aim of this study is to identify the drivers of robust projections in SH final 129 warming date, which will depend on the forcings, and the response to them, hav-130 ing the same characteristics across the model ensemble. As the turning points 131 in the ozone timeseries are comparable, it is anticipated that the qualitative 132 response of the final warming date to ozone will have similar characteristics 133 across the models. Hence, the quantitative differences in the ozone forcing are 134 not anticipated to influence our result. 135

To date, different numbers of ensemble members have been provided for each of the CMIP5 models. Where multi-model means have been used, they include only one ensemble member for each model to avoid biasing the mean towards models with a larger number of ensemble members.

ERA-Interim (Dee et al., 2011) and the NCEP Climate Forecast System Reanalysis (CFSR) (Saha et al., 2010) were used to assess biases in the model data.

¹⁴³ 2.1 Final warming diagnostic

The definition of vortex breakdown is subjective, and several approaches have 144 been used in earlier studies. These include potential vorticity-based spatial 145 diagnostics (Waugh and Randel (1999), Waugh et al. (1999), Karpetchko et al. 146 (2005), Zhou et al. (2000)), diagnostics based on wind thresholds (Black and 147 McDaniel, 2007), and temperature based diagnostics (Haigh and Roscoe, 2009). 148 However, regardless of the definition used, there is a consensus that the final 149 warming date (FWD) of the SH vortex was later in the 1990s compared to 150 the 1980s. Potential vorticity is not a standard CMIP5 output, and the coarse 151 vertical resolution of the archived data makes it difficult reliably to calculate 152 potential vorticity. Therefore, only temperature (Haigh and Roscoe, 2009) and 153 wind (Black and McDaniel, 2007) based diagnostics of the FWD have been 154 considered. 155

Black and McDaniel (2007) defined the FWD as the final time that the zonalmean zonal-wind at 60°S and 50 hPa drops below 10 ms⁻¹ until the following autumn. They apply the diagnostic to 5-day running averages of daily data.

Haigh and Roscoe (2009) define the FWD as the minimum in the second 159 time derivative of polar cap mean (90-60°S) temperature at 50 hPa. They use 160 3-day averages of daily and bi-daily data, smoothed with a 21-day triangular 161 filter. However, they found that interpolation of monthly mean data gave similar 162 fields to smoothed daily data. Here, monthly mean data is used as, at this 163 early stage in CMIP5, it facilitates the analysis of a larger number of models. 164 The sum of the first five Fourier components of the temperature time series 165 is used to produce interpolated daily data. Due to the smooth nature of the 166 evolution of the seasonal cycle in polar cap mean temperature, only negligible 167 differences were identified between FWDs calculated using this method, and 168 those calculated using daily data (see Figure 2). 169

The FWD calculated using the Haigh and Roscoe method is typically a week 170 earlier than that calculated using the Black and McDaniel diagnostic. However, 171 there is little qualitative difference between the diagnostics (Figure 2): the time 172 series are strongly correlated, with r=0.95 for 1950-2005 for CNRM-CM5 data. 173 The use of the Black and McDaniel (2007) threshold-based diagnostic may be 174 problematic if there are significant variations in the background state between 175 models, or under strong forcing. In some models, the use of the 10 ms^{-1} thresh-176 old results in non-identification of a FWD for some years in the historical period. 177 As scenarios with large forcing will be considered, the Haigh and Roscoe diag-178 nostic, from monthly mean data, will be used for the remainder of this work, in 179 order to avoid excessive non-identification of FWDs. 180

¹⁸¹ 2.2 Empirical mode decomposition

Climate data is often non-linear and non-stationary. Deviations from monotonic change are particularly apparent in the Southern Hemisphere where change is governed by the competing effects of increased greenhouse gases and stratospheric ozone. Changes in FWD have been established as being strongly ozone driven (Zhou et al. (2000), Karpetchko et al. (2005), Haigh and Roscoe (2009)), and a better fit is found between FWD and stratospheric ozone concentrations than can be achieved with linear trends for example (Haigh and Roscoe, 2009).

To avoid fitting extrinsic functions, which may not correspond well to the 189 non-linearity embedded in the data, or forcing data time series, which may 190 only account for changes via one of many mechanisms, Empirical Mode De-191 composition (EMD) has been used to analyse variability in FWD. EMD is an 192 intrinsic, adaptive method for deriving the variability of a time series on vari-193 ous timescales. EMD has successfully been applied to climate data in several 194 previous studies (e.g. Lee and Ouarda (2011), Franzke (2009), Huang and Wu 195 (2008), Wu et al. (2007), McDonald et al. (2007), and Duffy (2004)). While 196 EMD is a useful tool for analysing variability and trends in non-linear time se-197 ries, it cannot be used to unambiguously attribute particular characteristics of 198 these trends to a given forcing mechanism. Hence, EMD is used here alongside 199 multiple linear regression analysis. 200

EMD is an algorithm used to decompose a time series into a set of Intrinsic Mode Functions (IMFs), with each describing a given oscillatory mode of the data. IMFs must satisfy two conditions:

- Must have a local mean of zero
- Must have a single zero crossing between two extrema

IMFs are extracted sequentially from a data series, from the highest frequency
to the lowest, until no complete oscillation can be identified. The residual from
this process then describes the long-term trend in the data, where the trend is
defined as the instantaneous mean of the time series.

Unlike Fourier filtering, the phase and amplitude of each IMF are time dependent. The number of IMFs extracted from a time series is typically $\ln N$,

where N is the number of data points (Wu et al., 2007). There is some evi-212 dence of mode mixing (signals of different timescales identified in the same IMF) 213 amongst the IMFs of FWD from EMD. To avoid this, Ensemble Empirical Mode 214 Decomposition (EEMD) has been used. EEMD gives an ensemble mean of the 215 IMFs for the product of FWD and a finite white noise series (Wu and Huang, 216 2009). The inclusion of a noise series provides a uniformly distributed reference 217 scale, which preserves the dyadic property of EMD that can fail when data is 218 intermittent (Wu and Huang, 2009). The noise is cancelled out in the ensemble 219 mean, so it can be used to facilitate the separation of different timescales, with-220 out contributing to the final IMFs. EEMD is performed here with 200 iterations 221 and white noise with an amplitude of 0.2 times the standard deviation of the 222 FWD series (following Wu and Huang (2009)). 223

Figure 3(a) shows a time series of FWD from MIROC-ESM-CHEM under 224 RCP4.5, calculated using the Haigh and Roscoe (2009) method, alongside the 225 IMFs from EEMD (Figure 3(b)). Most of the high-frequency variability in the 226 time series, with a period of less than 3 years, is contained in the first two IMFs 227 (not shown). The local maximum near 2000 is captured in the sixth IMF, and 228 the increasing trend through the period shown is captured in the residual. The 229 equivalent result using EMD is shown in Figure 3(d). In this example, it can be 230 seen that the different frequencies have not been satisfactorily separated. This 231 is particularly clear in the third IMF (top line of Figure 3(d)), where the period 232 of the oscillation around the year 2000 is double that in the rest of the IMF. 233

IMFs that can be distinguished from the equivalent IMFs of a noise time 234 series of the same length are significant, and can be taken to represent physically 235 meaningful signals. White (Wu and Huang (2004), Wu et al. (2007)) and red 236 (Franzke (2009)) noise have both been used in previous studies to assign signif-237 icance to IMFs from climate data. There is no physical reason why the FWD 238 in one year would be dependent on the date in another year (Black et al. (2006) 230 also considered each event as an independent sample). Therefore, a comparison 240 with a white noise series has been used to determine when an IMF is significant, 241 following Wu and Huang (2004). 242

A significant difference from a white noise time series is identified through 243 analysis of the period (T) and energy density (E) of each IMF. Wu and Huang 244 (2004) show that the probability density function for each IMF of a white noise 245 time series is well approximated by a normal distribution, and that the prob-246 ability distribution of the energy of the nth IMF, NE_n , is a χ^2 distribution, 247 with $N\overline{E}_n$ degrees of freedom, where \overline{E}_n is the mean of E_n when the number 248 of data points, N, approaches ∞ . The spread of different confidence intervals 249 as a function of the mean energy of each IMF can then be determined. Wu and 250 Huang (2004) define $y = \ln E$ and show that for $|y - \overline{y}| \ll 1$, the distribution of 251 the energies is Gaussian. The spread lines can then be approximated by 252

$$y = -x \pm k \sqrt{\frac{2}{N}} e^{x/2} \tag{1}$$

where $x = \ln \overline{T}_n$, \overline{T}_n is the mean period, and k is a constant from the percentiles of the normal distribution. Example energies and periods from 1000 white noise time series of 1000 data points, and the spread lines from the 95% confidence interval, are shown in Figure 3(c). Energy densities from a data time series that lie outside the bounds of the spread lines can be assumed to be significantly different from those expected from a white noise time series, and are therefore expected to contain some information at that confidence level.

²⁶⁰ 3 Past and future trends in final warming date

Mean FWDs in the individual models are shown in Figure 4 for three periods: 261 1870-1900, 1979-2005, and 2070-2098. In most cases, the FWD is one to two 262 weeks later in 2070-2098 compared to 1870-1900. In the RCP4.5 experiment 263 the delay ranges from a change of 1 day in INMCM4 to 9 days in CanESM2, 264 CSIRO-Mk3.6.0, GISS-ES-R, and NorESM1-M (Figure 4(a)). In RCP8.5 the 265 delay compared to 1870-1900 ranges from 2 days in INMCM4 to 15 days in 266 CanESM2 (Figure 4(b)). With the exception of CNRM-CM5 and GISS-E2-R, 267 all models have later FWDs in 2070-2098 in the RCP8.5 experiment than in 268 RCP4.5. Figure 4(c) compares FWD from 1870-1900 to 2070-2098. There is 269 some evidence of a saturation effect here, with models with a very late historical 270 FWD appearing to show less of a change in the future. 271

Figure 4(d) shows the 1979-2005 mean FWD for each model, compared to ERA-Interim and CFSR. In all models except MIROC5, the FWD is too late compared to the reanalyses, with most models having an FWD that is significantly later. Such a late bias has been identified in earlier model evaluations, e.g. Butchart et al. (2011). It can also be seen in Figure 4(d) that most models underestimate the inter-annual variability in FWD compared to reanalyses.

The late bias in model FWDs is reflected in the high- and low-top ensemble 278 means, shown in Table 2, and in Figure 5 alongside those from ERA-Interim 279 and CFSR. The mean FWDs in the period 1979-2005 are day 312 and day 313 280 in ERA-Interim and CFSR respectively. The low-top mean FWD is around 2 281 weeks late, with a 1979-2005 mean of day 327. The high-top ensemble mean is 282 in better agreement with the reanalysis values, but is still late on average, with 283 a 1979-2005 mean of day 321 (Table 2). For all periods shown in Figure 4, the 284 mean FWD from the low-top ensemble is around a week later than that from 285 the high-top ensemble (Table 2). 286

The FWD from the low- and high-top ensemble is shown in Figure 6 for the historical and RCP4.5 and historical and RCP8.5 experiments. There is more inter-model spread and inter-annual variability in the low-top ensemble, although there is still a considerable amount of inter-annual variability in the FWD from the individual high-top models.

A marked delay in FWD can be seen in the high-top ensemble from the late 1970s to the late 1990s (Figure 6). This is associated with the localised, seasonal, cooling that results from ozone depletion in this period. Under RCP4.5 this increase in FWD is followed by a steady decrease to 2100, but in RCP8.5 a more modest decrease is seen, followed by a small trend towards later FWDs by 2100. The large inter-model spread amongst the low-top models makes such features difficult to distinguish in the low-top ensemble. However, there is some sense of a shift towards later FWDs in the late twentieth century.

The large interannual variability and inter-model spread in FWD makes 300 it difficult to compare patterns of behaviour across the models, although the 301 spread in absolute values is important to bear in mind. The FWD in all models 302 is now adjusted to the 1860-1900 mean to assist discussion of the change in 303 FWD across the models. In Figure 7, an 11-year running mean has also been 304 applied, which removes high frequency inter-annual variability, without obscur-305 ing decadal variability. The ensemble means shown in Figure 7 are calculated 306 by first finding the ensemble mean of the adjusted raw data, then calculating 307 the 11-year running mean. 308

More similarities can be seen in the behaviour of the low- and high-top 309 models in Figure 7 compared to Figure 6. A clear increase in FWD can now be 310 seen in the low-top ensemble, although the change is not as rapid, large, or as 311 consistent across models, as in the high-top ensemble. A return to earlier FWDs 312 in the twenty-first century can now be seen in the low-top ensemble mean under 313 RCP4.5, although the rate of change is still small compared to that seen in 314 the high-top ensemble. Under RCP8.5, the FWD in the low-top ensemble mean 315 shows very little change in the twenty-first century. In contrast, a clear decrease 316 can be seen in the first half of the twenty-first century in the high-top ensemble, 317 followed by an increase towards the end of the century. The large twenty-first 318 century inter-model spread in the low-top ensemble, even after adjusting to the 319 1860-1900 mean, may obscure some of this behaviour in the low-top ensemble 320 mean. However, there is no convincing evidence of such a pattern in the FWDs 321 from individual models. Such behaviour can be seen in a number of the high-top 322 models. 323

³²⁴ 4 Drivers of past and future trends in final warm-³²⁵ ing date

The primary drivers of changes in FWD are anticipated to be changes in strato-326 spheric ozone and well-mixed greenhouse gas concentrations. These changes will 327 occur on different timescales, and have different functional forms in the time-328 series. As such, their signature can be expected to be seen in different IMFs. 329 Increasing greenhouse gases are expected to be linked to a delay in the FWD, 330 while the depletion and recovery of stratospheric ozone will produce a delay fol-331 lowed by an advance: a signature with a period in the region of 60 years. These 332 responses are likely to be seen in the residual and the last IMF respectively. Fig-333 ure 1(b) shows that the largest changes in stratospheric ozone concentrations at 334 southern high latitudes occur in the first half of the twenty-first century. Hence, 335 it is anticipated that changing ozone concentrations will be the primary driver 336 of FWD changes here, with greenhouse gases becoming increasingly important 337 in the second half of the century. Figure 1(a) shows that greenhouse gas con-338 centration changes in RCP4.5 and RCP8.5 are very different in the latter half 339

of the century, with almost no change in concentrations in RCP4.5 and rapid increases in RCP8.5. The potential influence of this difference on FWD was hinted at in Figure 7. It is particularly clear in the comparison of the high-top ensemble means for the two scenarios, where a negative trend from ~ 2070 is seen in RCP4.5 and a positive trend is seen in RCP8.5.

The sum of the residual and the last IMF for each model, and the low-345 and high-top ensemble means, are shown in Figure 8. The ensemble mean is 346 calculated by finding the ensemble mean of the adjusted data, then performing 347 EEMD on this mean. All models and the ensemble means show, with the 348 exception of MIROC5, later FWDs around the turn of the century, under both 349 RCP4.5 and RCP8.5. Patterns of behaviour seen in the ensemble mean are 350 similar to those seen in the running means in Figure 7: an increase then decrease 351 in FWD under RCP4.5; and an increase then decrease then increase in the high-352 tops under RCP8.5. There is even a suggestion of this RCP8.5 response in the 353 low-top models HadGEM2-ES and CSIRO-Mk3-6-0. However, the amplitude 354 of twenty-first century changes are smaller in the low-top ensemble than 355 the high-top case. The larger response of high-top models to greenhouse gas 356 forcing towards the end of the twenty-first century is consistent with the larger 357 temperature gradient changes at the tropopause level simulated by these models 358 (Wilcox et al., 2012). 359

Significance testing was carried out to determine which IMFs show patterns 360 significantly different to those that may be identified in a white noise time series. 361 The Wu and Huang (2004) method was used, including their assumption that 362 the energy of the first IMF comes solely from noise and can be used to re-scale 363 the energy density of the other IMFs. Figure 9 shows the sum of significant IMFs 364 (at the 5% level) with periods greater than 50 years (in order to consider only 365 inter-decadal variability) for the low- and high-top ensemble mean (Figure 9 (a) 366 and (b) respectively). The signatures of the high- and low-top significant IMFs 367 follow the patterns seen in the running means, and sums of the last two IMFs: a 368 more pronounced peak at the turn of the century in the high-top ensemble, and 369 a trend towards later FWDs at the end of the twenty-first century in RCP8.5 370 in the high-top ensemble only. 371

The spread function of the 95% and 99% confidence intervals for white noise and energies of the individual IMFs are shown in Figure 10. Here, a significant IMF is identified when it lies outside the inner pair of dotted lines, which indicate the 5th and 95th percentile for white noise. The outer pair of dotted lines indicate the 1st and 99th percentile.

Figure 10 shows that the residual is clearly significant for both ensembles 377 and scenarios. For the high-top ensemble, the last IMF is also significant at the 378 1% level for both scenarios. In a reflection of the larger inter-model spread, and 379 the resulting weaker peak in FWD around the turn of the century, the last IMF 380 of the low-top ensemble mean is significant at the 5% level for the historical 381 and RCP4.5 scenario, and not at all for the historical and RCP8.5 scenario 382 (Figure 10(b)). The higher energy of the last IMF in RCP8.5 in the high-top 383 mean compared to the low-top mean is not due only to a differing response to 384 ozone forcing. Analysis of the structure of the IMFs shows that in the high-top 385

RCP8.5 case the last IMF includes some response to GHG forcing, in addition to the anticipated ozone response. The delay in FWD towards the end of the twenty-first century is incorporated in the last IMF as the timing of the trend fits with the ~ 60 year period of the response to stratospheric ozone changes.

Multiple linear regression analysis was also performed, regressing FWD against 390 a constant, a timeseries of September to November mean Antarctic mean ozone 391 at 50 hPa, and $\ln(GHG)$, where GHG is represented by the CO₂ equivalent 392 values shown in Figure 1(a). Following Roscoe and Haigh (2007), these indices 393 are normalised to allow direct comparison of the regression coefficients. The re-394 gression slope, Pearson correlation coefficient, and significance from a two-tailed 395 student's t-test are shown in Table 3 for the high- and low-top ensemble mean 396 for RCP4.5 and RCP8.5. For ensemble mean calculations, ozone was taken from 397 the Cionni et al. (2011) data. 398

In both scenarios, FWD has a stronger relationship with both the GHG index and the ozone index in the high-top ensemble. This can be seen in the larger regression slopes and linear correlations shown in Table 3, and in comparison of the multiple linear correlations: 0.63 (0.64) and 0.76 (0.78) for RCP4.5 (RCP8.5) for the low- and high-top ensemble mean respectively. This is a reflection of the more consistent cross-model behaviour seen in the high-top models (e.g. Figure 8).

There is little difference between RCP4.5 and RCP8.5 in the statistics relat-406 ing to the ozone index (Table 3). The more influential role of GHGs in RCP8.5 407 is reflected in the regression slopes as well as the significance. The larger regres-408 sion slope, linear correlation, and significance associated with the GHG index 409 in RCP8.5 for the high-top ensemble compared to the low-top is likely to be 410 a reflection of the delay in FWD in the high-top ensemble mean near the end 411 of the twenty-first century in response to GHG forcing, which is not seen in 412 RCP4.5, or the low-top ensemble mean. This echoes the higher energies found 413 in the last IMF and residual of the high-top ensemble mean in RCP8.5. 414

In the illustrations of FWD in CMIP5 models shown in this study, MIROC5 415 has been a clear outlier. The model shows almost no change in FWD from 1860 416 to 2100 (Figure 4, Figure 7) and the structure of the timeseries from the sum 417 of the last IMF and the residual mirrors those from other low-top models. In 418 the high-top ensemble, there are no such striking outliers (Figure 8). However, 419 MIROC-ESM-CHEM shows larger inter-decadal variations in FWD than other 420 models in the group. While the behaviour of FWD in MIROC-ESM-CHEM is 421 not especially unusual in the context of the other models, is it possible that the 422 large changes simulated by MIROC-ESM-CHEM and the very small changes 423 from MIROC5 have enough influence on their respective ensemble means to 424 dominate the differences seen between the high- and low-top ensembles? 425

It was found that removing the MIROC models from the ensembles had no effect on our conclusions from EEMD analysis at the 5% level. As one would expect, there are small changes to the energies of the IMFs as a result of the removal, but the IMFs identified as being significantly different to those expected from white noise are the same, and their structure is qualitatively unchanged.

⁴³¹ The results of the multiple linear regression analysis without the MIROC

models is shown alongside the results for the whole ensemble in Table 3. As 432 expected, removing MIROC5, a model that shows little change in FWD, from 433 the low top ensemble slightly increases the correlation between the FWD and 434 both ozone and ln(GHG) in both the RCP4.5 and RCP8.5 case, but not to such 435 an extent that the significance level is altered. The removal of MIROC5 results 436 in an increase in the magnitude of the regression slope for the ozone index, and 437 for the GHG index in the RCP8.5 scenario. It also brings the regression slope 438 for the GHG index closer to the anticipated positive value in the RCP4.5 case. 439 MIROC-ESM-CHEM simulates a slightly larger response to stratospheric 440 ozone depletion compared to the rest of the high-top ensemble, but doesn't 441 show a delay in FWD towards the end of the twenty-first century. Thus, it is 442 anticipated that the removal of the model from the high-top ensemble will result 443 in a decrease in the magnitude of the regression slope of the ozone index and 444 correlation, and an increase in the regression slope and correlation for the GHG 445 index. Such changes can be seen in both the RCP4.5 and RCP8.5 case (Table 3). 446 These changes are marked enough to decrease the significance of the relationship 447 between stratospheric ozone and RCP8.5 FWD, and of the relationship between 448 RCP4.5 FWD and GHG. 449

As one would expect, removing the MIROC models from the analysis does 450 change the statistics. However, the conclusions drawn from the analysis are un-451 changed. The importance of stratospheric ozone changes as a driver of changes 452 in FWD is consistent across both scenarios, with a unit change in ozone concen-453 tration having more influence on the high-top ensemble mean than the low-top 454 ensemble mean. GHG changes play more of a role in RCP8.5 than RCP4.5, and, 455 as for ozone changes, result in a larger change in FWD in the high-top ensemble 456 mean than the low-top mean. The larger values of the regression coefficients in 457 the high-top case reflect the higher energies of the residual and last IMF seen 458 in Figure 10, and the more consistent behaviour of the models seen in Figure 8. 459

460 5 Conclusions

⁴⁶¹ Changes in final warming date are known to drive persistent tropospheric anoma-⁴⁶² lies with a similar structure to the southern annular mode (Thompson et al. ⁴⁶³ (2005), Black et al. (2006)). Such changes are sensitive to external forcing ⁴⁶⁴ from greenhouse gases and, in particular, stratospheric ozone. This results in ⁴⁶⁵ pronounced changes in Southern Hemisphere final warming date, with a peak ⁴⁶⁶ around the year 2000, which can be expected to influence spring and summer-⁴⁶⁷ time trends in high-latitude surface climate.

The Southern Hemisphere final warming date is around one week too late
in CMIP5 high-top models, and two weeks too late in low-top models compared to ERA-Interim and the Climate Forecast System Reanalysis (1979-2005).
The high-top models show more consistent absolute values and changes in final
warming date in both the historical and future periods than low-top models

After adjustment to the 1860-1900 mean, similar behaviour can be seen in both the high- and low-top ensembles. A shift to later final warming dates

is seen in the historical period as a response to stratospheric ozone depletion, 475 and a return to earlier final warming dates occurs as ozone recovers. In the 476 high-top ensemble, there is also a shift towards later final warming dates in the 477 latter half of the twenty-first century in RCP8.5, which is consistent with the 478 larger meridional temperature gradient identified in high-top models by Wilcox 479 et al. (2012). The high-top models show a more consistent pattern of change, 480 and larger changes, in response to forcing compared to the low-top models. 481 This difference is apparent in both the comparison of significant IMFs, and the 482 coefficients from multiple linear regression. 483

Further investigations with larger ensembles of high- and low-top models, 484 with consistent ozone concentrations, are required. Simpson et al. (2011) showed 485 that the late bias in final warming date contributes to too-persistent southern 486 annular mode anomalies in summer, and may cause models to respond too 487 strongly to anthropogenic forcing in this season. Hence, the difference between 488 the high- and low-top ensemble mean results, the large spread in the low-top 489 ensemble, and the more pronounced late bias in final warming date in the low-490 top ensemble, suggest that high-top models are likely to be required to produce 491 accurate projections of future Southern Hemisphere surface climate. 492

493 6 Acknowledgments

This work was funded by the National Centre for Atmospheric Science (NCAS) Climate via a CMIP5 grant.

We acknowledge the World Climate Research Programme's Working Group on Coupled Modelling, which is responsible for CMIP, and we thank the climate modelling groups for producing and making available the model output listed in Table 1. For CMIP the U.S. Department of Energy's Program for Climate Model Diagnosis and Intercomparison provides coordinating support and led development of software infrastructure in partnership with the Global Organization for Earth System Science Portals.

We thank the British Atmospheric Data Centre (BADC) for providing access to their CMIP5 data archive, and acknowledge the use of ERA data made available by the BADC and NCAS-Climate. NCEP/NCAR data was provided by NOAA/OAR/ESRL PSD, and CFSR data was provided by NCAR, via the Research Data Archive (RDA).

⁵⁰⁸ We also thank three anonymous reviewers for their helpful suggestions.
