Thus the proposed model can be represented with the following equation:

$$\ln(y) = 4.923 + 0.881 \ln(x_1) – 0.361\, x_2 – 0.054 \ln(x_3) – 0.160 \ln(x_4)$$

where:

y = construction speed (m^2 gross external floor area/month)

x_1 = project size

x_2 = number of winters

x_3 = type of use – office

x_4 = type of use – other

Residential was chosen as defaults for type of use.

The back-transformed regression equation reads:

$$y = e\^(4.923) * e\^(0.881 \ln(x_1)) * e\^(–0.361x_2) * e\^(–0.054 \ln(x_3) * e\^(–0.160 \ln(x_4))$$

The explanatory contents of the drivers/independent variables that have been included vary. Using a univariate variance analysis, a rank order can be identified, which is shown in the variable sequence in the proposed equation. The greatest explanatory content can be identified for the variable ‘project size’ and the smallest content for ‘type of use’.

Causal relationships in the regression model

The causal relationships of each independent variable of the proposed model are described in the following section. It begins with the project size (measured in 1000 m^2 gross external floor area), whose impact on construction speed is represented in Figure 3. This driver/independent variable contributes the largest explanatory content, which can be quantified on the basis of the regression equation:

- If x_1 (project size measured in 1000 m^2 gross external floor area) increases by 1%, then construction speed rises by approximately 0.88%.

An average property of the available sample has approximately 11 400 m^2 of gross external floor area and a construction speed of approximately 493 m^2 gross external floor area/month. If the absolute size of this average property increases by 3000 m^2 gross external floor area (26%), the construction speed rises by approximately 23%. The construction speed indicator of an equivalent 14 400 m^2 gross external floor area property amounts therefore to 606 m^2 gross external floor area/month.

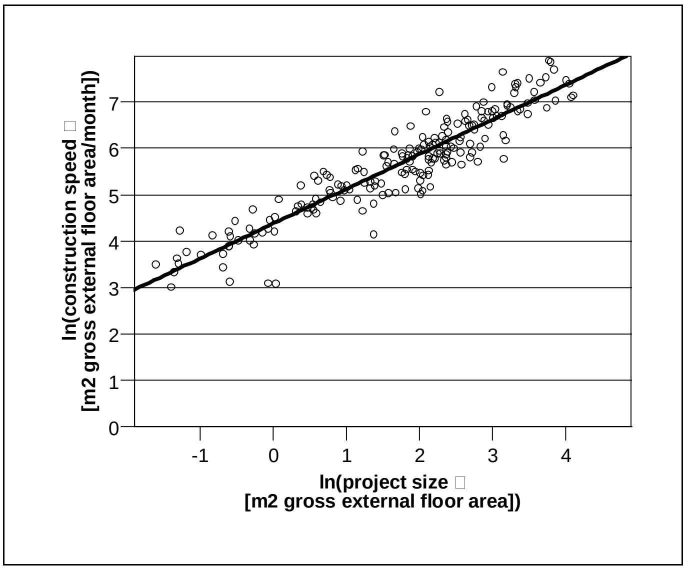

Figure 3: ln(construction speed [m^2 gross external floor area/month]) and ln(project size [1,000 m^2 gross external floor area]) (R = 200)

In contrast to the project size, the number of winters exhibits a negative speed impact (Figure 4). This means that construction speed (m^2 gross external floor area/month) decreases with an increasing number of winters during the construction process:

- According to the back-transformed regression equation it can be stated that an additional winter decreases the construction speed by approximately 30% (y = e^(–0.361 * 1)y = 0.697y).

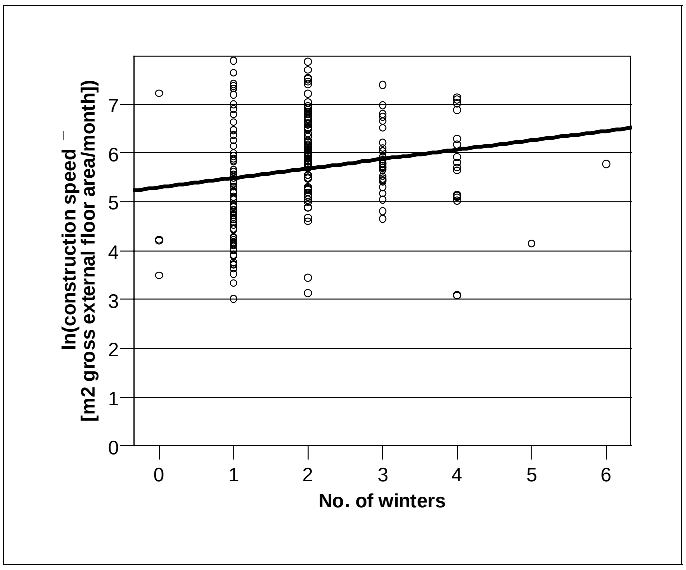

Figure 4: Construction speed and number of winters (R = 200)

The above-mentioned speed drivers are metrically scaled. In contrast, the driver ‘type of use’ (differentiated between office, residential and other) is ordinal-scaled. Therefore two dummy variables (x_3, x_4) are incorporated in the proposed model to include this speed driver. ‘Residential’ is chosen as default attribute. The following causal relationships of this driver can be quantified according to the back-transformed equation:

- ‘Office’ projects (x_3) are slower than ‘residential’ projects (approx. 5% according to the coefficient of –0.054).
- ‘Other’ projects (x_4) are slower than ‘residential’ projects (approx. 15% according to the coefficient of –0.160).

This study predominantly confirms preceding studies with the three described speed drivers. For example Love *et al.* (2005) also recognized the high influence of the project size, which is measured in m^2 gross external floor area, and they also presented a log-log regression model. On the other hand the present study supplies another driver which has received no attention so far: number of winters. This driver is shown to be relevant even if their relevance remains far less than that of project size (cf. Love *et al.* 2005).

CONCLUSION

With this study the relevant construction speed drivers are identified on the basis of 200 Swiss properties, and their causal relationships are presented in a log-log regression model. This proposed model shows a mean absolute percentage error (MAPE) of 16% and integrates the following independent variables (speed drivers):

- project size (1000 m^2 gross external floor area);
- number of winters;
- type of use (office, residential, other) (dummy).

In addition the model shows its comparatively good prognostic accuracy with the test of 25 properties which were not included in the development of the proposed model. The percentage error for these test properties lies between –39% and 25%.

Owing to limits of the available data, a set of further construction speed drivers could not be examined. Essentially these are the so-called ‘soft’ factors which Walker (1995) examined, for example:

- client objectives;
- management style;
- communication between architect/engineer and contractor;
- use of information technology.

ANALYSIS ON COMPREHENSIVE ASSURANCE OF CONSTRUCTION SCHEDULE FOR HYDROPOWER PROJECT

Liu Quan,[1] Hu Zhigen, Wang Jing and Fan Xi-e

State Key Laboratory of Water Resource and Hydropower Engineering Science, Wuhan University, Wuhan, HuBei, China

Generally, hydropower projects come with huge investment, complex construction conditions and many uncertain construction factors; hence, the research on construction risk or construction assurance is indispensable. The risk of construction schedule is the completion date of partial or whole project passes beyond the specified date. Commonly, the risk for dam constructing schedule means the risk of dam construction reaching specified levels before specified deadlines. Since the risk neglects the duration uncertainty of the working procedure and whole project, the results of risk of dam constructing schedule is lower or more optimistic than that what brings dangers to decisions and projects. Based on the analysis of the flaw in the risk of the dam construction schedule, taking into account the uncertainties in hydrological, hydraulic, and construction schedules factors, the concept of comprehensive assurance of construction schedules on dams for hydropower projects is prompted, and its calculation model is built up. By means of Monte-Carlo method and computer simulation technology, those uncertainties are synthesized into the comprehensive assurance. An instance shows that the comprehensive assurance of dam construction is a more comprehensive index to describe the risk factors of the hydropower project construction.

Keywords: risk analysis, construction planning, process modelling, Monte Carlo simulation.

INTRODUCTION

Generally, hydropower projects come with huge investment, complex construction conditions and many uncertain construction factors; hence, the research on the construction risk or the construction assurance is indispensable. In recent years, Chinese and foreign scholars have made many research achievements. The method is extended from PERT simulation to Monte-Carlo simulation (Lee 2005) or other methods (Guo 2001), and the construction duration evaluation method is extended from simple CPM to kinds of simulation method (Lu 2000). Bonnal (2004) introduces fuzzy project scheduling into the analysis of working procedure duration. In view of the uncertainty of working procedure duration, Hu (1999), Xu (1998) and Wang (1999) assume that it submits to a specified random distribution, based on the construction and experience, gains the estimation of total construction progress and the statistical distribution characteristic through network planning progress Monte-Carlo simulation and, consequently, gains the risk distribution of total construction progress. The flood impact of the flood season should also be taken into account during the construction progress of the dam. We cannot ensure which type of

[1] hapland@163.com

distribution the working procedure duration submits to. Aiming at the uncertain factors of floor peak flow, Wang (2002) researches the probability characteristic of the water level before the cofferdam, and computes the progress assurance rate of the cofferdam filling elevation by month. The progress assurance rate is calculated on the base of the cofferdam filling elevation by month, while the uncertainty of working procedure duration in the construction progress ensures that the completion time of the cofferdam filling elevation is uncertain too. It shows that above progress assurance rate is computed without considering the impact of the uncertainty of construction duration. Hence, the network progress risks and dam filling progress risks are combined to make a further analysis of dam construction progress risks, and promote the index of dam construction progress comprehensive assurance rate.

ANALYSIS OF CONSTRUCTION SCHEDULE RISK

The risk of construction schedule (Hu 1999) is the probability that the calculated partial or whole project completion date T_c of the project network programming passes beyond the specified date T_p. The mathematic expression of construction schedule risk P_r is:

$$P_r = P(T_C > T_p) \tag{1}$$

Assume that working durations are subject to a specified parameter of specified random distribution of certain types, and the computer will produce a random number as working duration according to the type of random distribution and distribution parameters on simulating, then some parameters such as the project duration, the start time and end time of each working procedure by the construction network time parameter calculation. Construction period, the probability distribution and average of every key period can be gained by simulation. The simulation flowchart of construction schedule risks by Monte-Carlo method is shown in Figure 1.

ASSURANCE ANALYSES ON DAM SHEDULE

As a specified of hydropower engineering, the dam is a time-consuming project that experiences years generally and flood flux changefully, a random process due to the uncertainty time and the flood peak flow in riverbank. At the meantime, there is uncertainty in the discharge ability of diversion structures. Consequently, it is important to figure out a reasonable plan for dam project process, which the dam should be built higher than upstream water level to ensure the dam construction, especially in the process of midterm diversion with dam retaining water.

The assurance analysis on dam schedule can be defined as the probability of the actual water level being lower than the dam elevation at that time (Hu 2002). This is presented as:

$$R_Q = P(Z_u(t) < H_u \tag{2}$$

where $Z_u(t)$ is the upstream water level in the t month, and H_u is the design upstream water level before dam.

The dam project schedule is affected by the flood process and the effusion ability of diversion structures. In order to get the upstream water level random distribution, the uncertainties of flood characters and the discharge hydraulic conditions should be considered, and random flood routing calculation be employed to get the result (Zhong 2005).

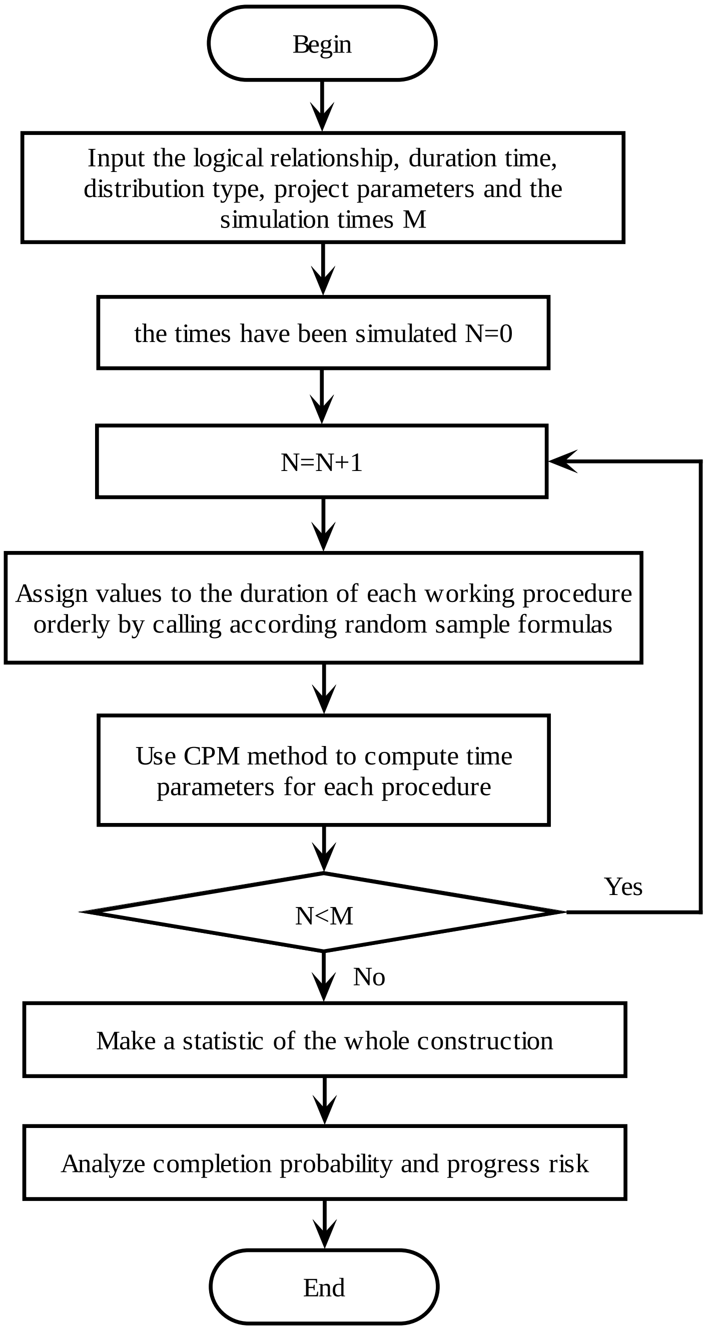

Figure 1: The flowchart of construction schedule risk by Monte-Carlo simulation method

The flood peak values subject to P-III distribution in general hydrology calculation (it is recommended by the Chinese national standard). Using peak values to amplify typical flood process and other hydrology random factors are ignored. Since discharge abilities of discharge structures are affected by kinds of random factors, only the channel roughness factor on discharge abilities is taken account for its remarkable degree, and follows the triangle distribution on the assumption. Other hydropower factors are ignored in the random simulation model. The simulating flowchart of assurance rate of dam construction schedule by Monte-Carlo method is shown as Figure 2.

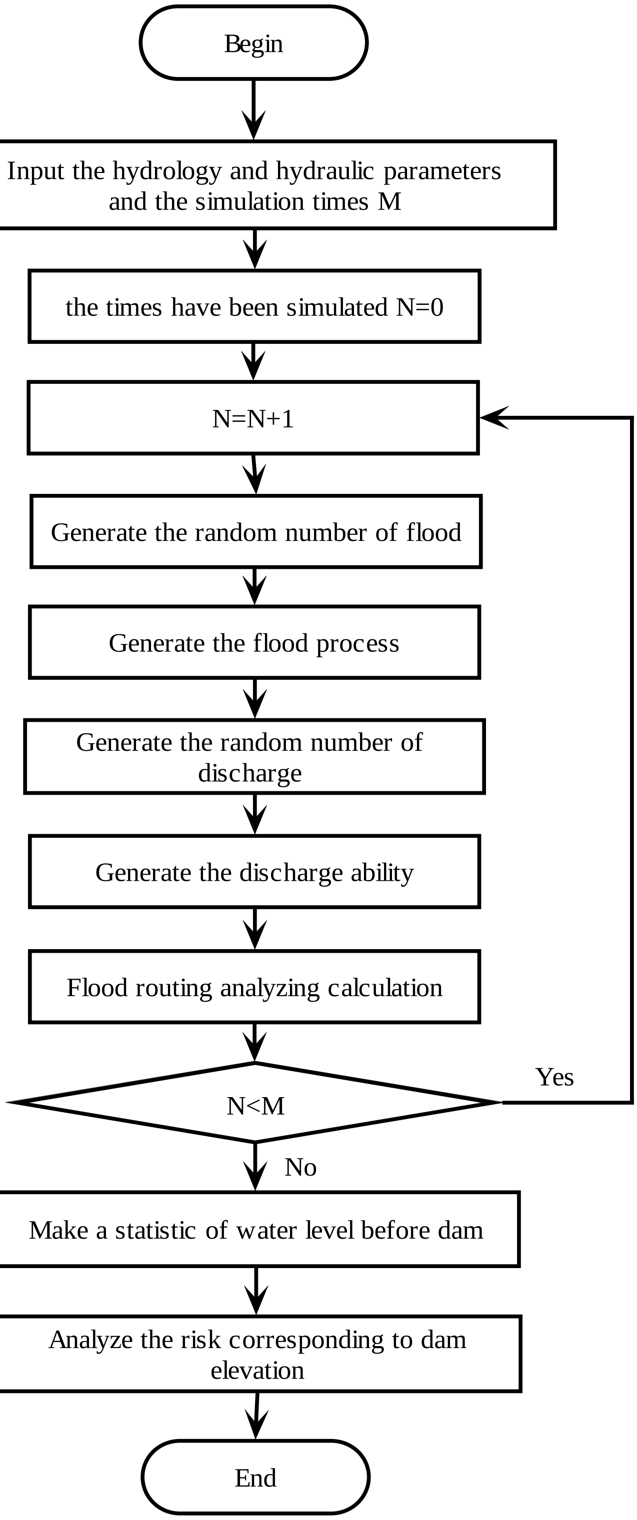

Figure 2: The flowchart of assurance rate of dam construction schedule by Monte-Carlo simulating method

ANALYSIS OF HYDROPOWER DAM CONSTRUCTION PROGRESS COMPREHENSIVE ASSURANCE RATE

Analysis of the uncertainties of construction progress network

During the process of dam construction, schedule curve of the dam H-T_p is usually used to show the relationship between the practical dam elevation and the design schedule, as Figure 3 shows. H_1, H_2, H_3 is the control elevation of dam construction in the following figure.

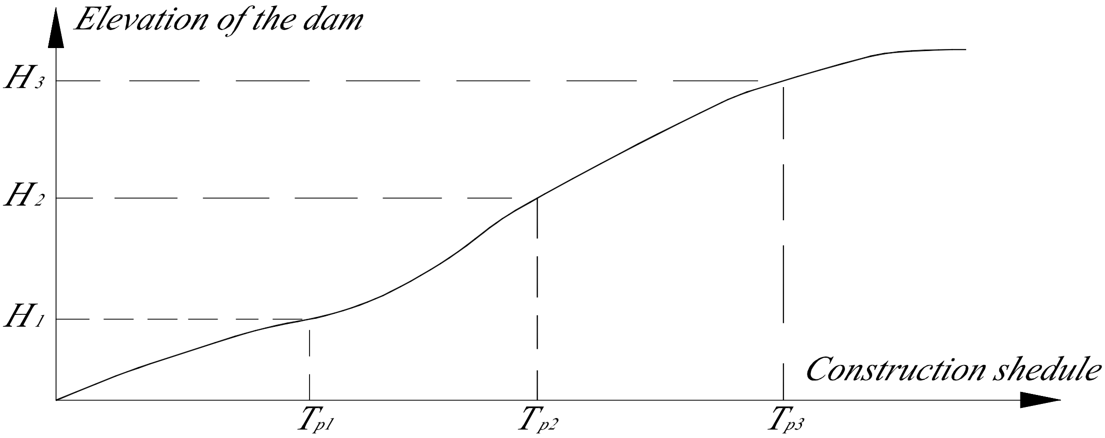

Figure 3: The schedule curve of the dam image

According to the definition of construction schedule risk P_r, we can define the completion assurance rate of construction schedule as:

$$R_T = 1 \Phi P_r, \quad R_T = P(T_C \mathrm{A} T_p) \tag{3}$$

where T_c is the practical / simulation construction schedule; T_p is the plan schedule.

As a specified dam project, based on Monte-Carlo simulation analysis of planning schedule network, it is risky that dam reaches a specified elevation in the specified completion date. The completion assurance rate curve R_T-T_p for each procedure is drawn. The dam elevation H is correspondent to completion assurance rate R_T, as the H growing, the construction are getting more, the uncertain factors impacting on construction are getting more and more, thereby the completion assurance rate of dam is getting lower. Figure 4 is the construction procedure completion assurance rate curve of reaching the elevation H_1.

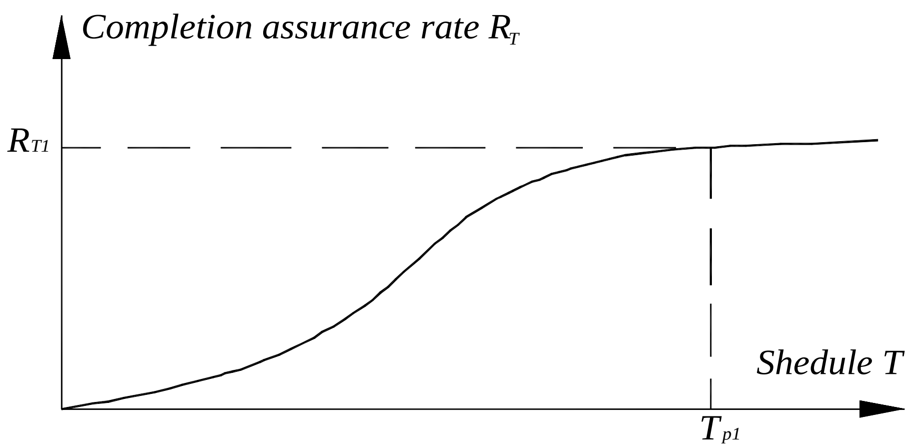

Figure 4: Control elevation H_1 completion assurance rate curve

The relationship between the dam elevation H_1 and completion assurance rate R_T is shown in Figure 5.

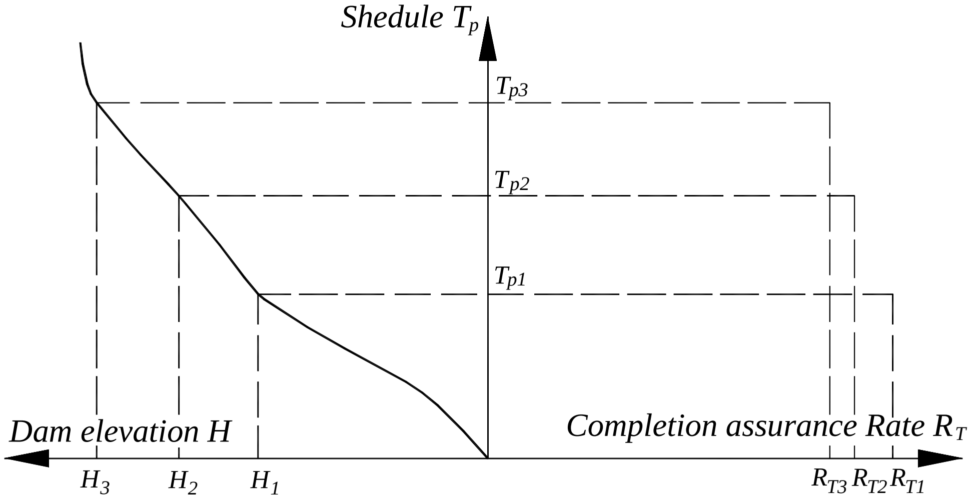

Figure 5: The relationship of the dam elevation *H* and completion assurance rate R_T

The flaw of assurance analysis on dam schedule
Dam schedule assurance R_Q is calculated by a certain designed water lever before-dam, which deems that the height of dam H_{dam} referring to the designed water level can be achieved within the time limit certainly. However, the random features of working procedure duration make uncertainties of the project schedule network. In fact, there is a risk of the dam reaching the specified height within the time limit. Therefore, it is not wise to calculate with a fixed H_{dam} value.

The comprehensive assurance rate of hydropower project construction schedule
Based on the previous analysis, if *R* is the assurance rate of hydropower project construction schedule, *H* is a certain specified height in the project schedule, then the assurance rate of dam schedule R_Q can be presented as $R_Q = f(R|H)$, and assurance rate of reaching specified elevation R_T can be presented as $R_T = f(H)$.

According to the conditional probability formula, there is: $f(R) = f(R|H)\,f(H)$. The standard of comprehensive assurance rate of project schedule is shown as:

$$R_Z = f(R) = f(R|H)\,f(H) = R_Q \times R_T \tag{4}$$

R_Z comprehensively reckons the uncertainties of the hydrology and hydraulic factors in the diversion process, as well as the uncertainty of the project schedule, and supplies the flaws using of R_T and R_Q independently, and thus provides a more reasonable way to evaluate the risk factors in the project process and more effective way to show the assurance rate of project schedule.

INSTANCE OF PROJECT

There is a hydropower project with a clay core rock fill dam as main retain water structure, left bank open spillway, left bank discharge tunnel, right bank discharge tunnel, downstream bank protection and left bank underground diversion system and hydropower station etc. The installed capacity of the station is 5850MW, and the capacity of the reservoir is about 225×10^8m^3. The elevation the dam top is 820.0m, the height of the dam is 261.5m, the normal sluice elevation is 812m, and dead water elevation is 760m. In the initial term diversion it is adopted that river would be closured in one session, earth-rock fill cofferdam retains water for whole year, and tunnel discharges flood.

Based on practical and experience, the channel roughness the three control parameters for discharge building are taken as (0.014, 0.015, 0.017) (parameters of triangle distribution). Some procedures' parameters are listed in Table 1, and other parameters are omitted for briefness.

Table 1: The some procedures' parameters

Procedure number	**Procedure name**	**Precedence number**	**Duration distribution (d) N(μ, σ) [min, max]**
0	start	-	0
1	Spillway bucket lip segment earth and sand-gravel excavation	0	N(93□12.6)[78□110]
2	approach channel earth and sand-gravel excavation	0	N(62□9.8)[50□78]
3	approach channel, weir shutter rock excavation	2	N(145□30.6)[128□176]
4	Channel excavation, underground excavation	3	N(30□5.6)[25□38]

For the result precision, based on construction schedule simulation model with Monte-Carlo method, 400 construction periods are gained by 400 times simulation. The minimum construction period is 3447days (11 years and 2 months), and the maximum is 3509 days (11years and 8 months). The average is 3439 days (11 years and 5 months), the average variance of which is 27.7 days. The completion assurance curve can be found in Figure 6; the construction period assurance rate R_T of 11.5 years design scheme is about 71.8%.

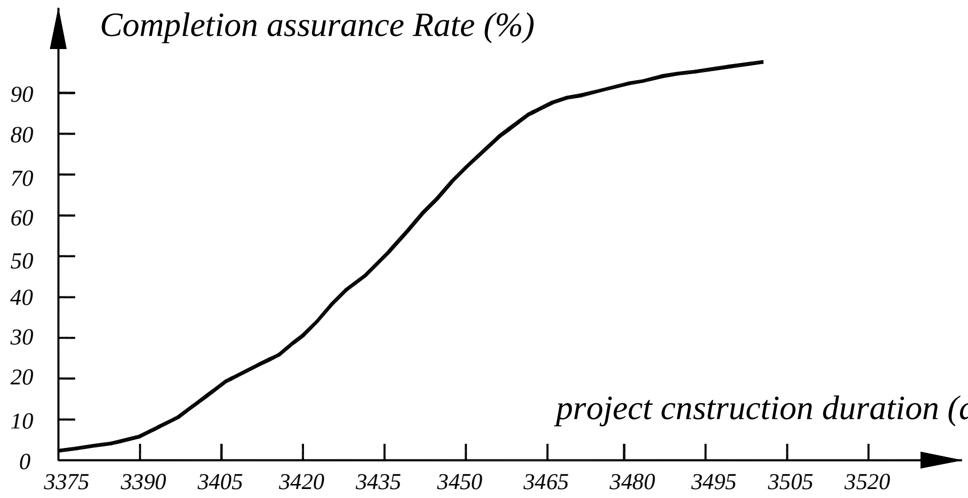

Figure 6: The completion probability curve of the whole period

The preconditions of generating electricity are that reservoir impoundment reaches the design elevation and the generator sets have been built up. The completion assurance rate of primary impoundment period is showed in Figure 7; the assurance rate of the reality of the construction period R_T corresponding 11.5 years (2493 days) is 81.5%.

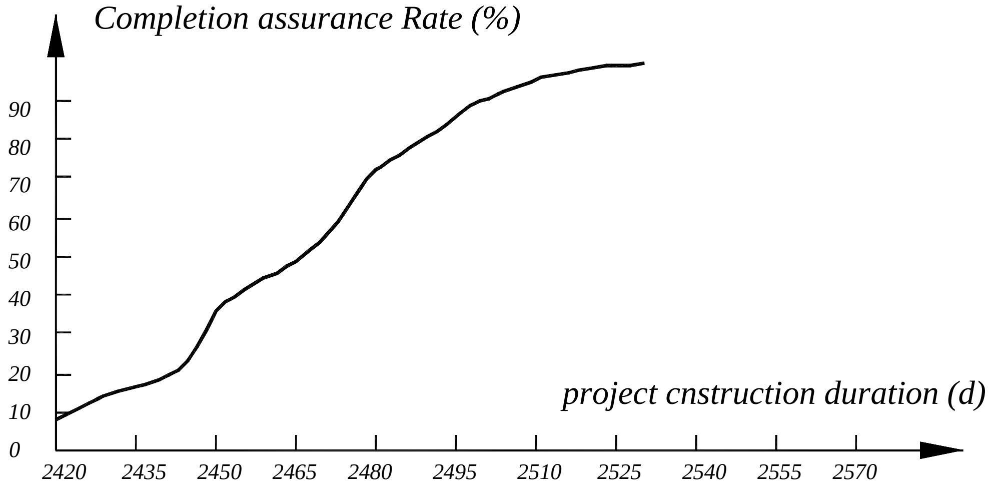

Figure 7: The completion probability curve of initial impoundment

The completion assurance rate of the first generator set generating electricity is showed in figure 8, the realizing assurance rate corresponding to the design construction period R_T 11.5 years (2575 days) is 72.5%.

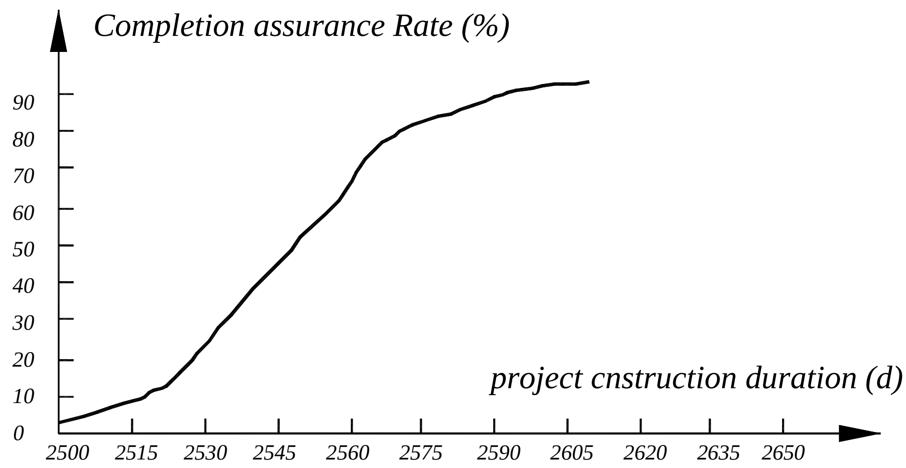

Figure 8: The completion probability curve of the electricity generating period of the first turbine generator set

Table 2: The simulation risk on design water level

Flood return period (year)	Upstream water level by design (m)	Hydrology random		Hydrology and hydraulic random	
		Risk	Assurance	Risk	Assurance
200	672.75	0.335%	99.666%	0.314%	99.686%
300	677.94	0.184%	99.816%	0.182%	99.818%
500	807.12	0.077%	99.923%	0.058%	99.942%
1000	808.67	0.012%	99.988%	0.014%	99.986%

According to hydrology series, the size of diversion structure, construction duration and hydrology and hydraulics etc., uncertain factors, and referring the planning, once the dam raises to 680m elevation in the sixth year before the flood, the dam begin to retain water, this period is called midterm diversion. In this period, the return period of design flood is 200 years, and corresponding flood peak flow is 22000m^3/s. The return period of exceptional flood is 300 years, and the corresponding flood peak flow is 23400m^3/s. In the late term diversion, which is 9th year, the flooding return period is 500 years, corresponding flood peak flow is 25100m^3/s; the exceptional flood is 1000 years, corresponding flood peak flow is 27500m^3/s.

As shown in Table 2, midterm diversion, the dam elevation comes to 680m, and reservoir impoundment. Taking into account of hydrology and hydraulic risk in the diversion period, the possibility that the upstream water level is lower than dam elevation at that time is schedule assurance rate R_Q, is 99.686%. When the elevation of the dam comes to 812m, the first generator set generates electricity. In the late term diversion, flood return period is 500 years and schedule assurance rate R_Q is 99.942%.

Take the uncertainty of construction schedule duration and hydrology and hydraulic risk into account, initial impoundment comprehensive assurance rate:

$R_Z \quad R_T \times R_Q \quad 81.5\% \times 99.686\% \quad 81.24\%$

The comprehensive assurance rate (the first generator set generating period):

$R_Z = R_T \times R_Q \quad 72.5\% \times 99.942\% \quad 72.46\%$.

CONCLUSION

Based on analysis of construction schedule risks and dam construction assurance, taking account of the uncertain factors of hydrology, hydraulic and construction schedule duration, the concept of comprehensive assurance of construction schedule for hydropower project is promoted. A case shows that the comprehensive assurance is smaller than schedule assurance deduced from either construction network schedule uncertainty or hydrology and hydraulic risks. It is shown that the comprehensive assurance of hydropower project construction schedule can represent the risk in the construction process more comprehensively and reasonably.

AN S-CURVE BAYESIAN MODEL FOR FORECASTING PROBABILITY DISTRIBUTIONS ON PROJECT DURATION AND COST AT COMPLETION

Byung-cheol Kim[1] and Kenneth Reinschmidt

Texas A&M University, 3136 TAMU College Station, Texas, TX77843-3136, USA

Forecasting is a critical component of planning, controlling and risk management for construction projects. In order to support effective project execution and control, project managers must be able to make reliable predictions about the final project duration and cost of projects starting virtually from project inception. The objective of this research is to develop probabilistic forecasting models that integrate all relevant information and uncertainties into consistent predictions in a mathematically sound procedure usable in practice. A Bayesian adaptive forecasting framework using S-curves has been developed. The primary advantages of this new approach against conventional methods such as the critical path method and the earned value method are threefold. It is (1) a probabilistic method that provides confidence bounds on predictions; (2) a consistent method that is applicable to both schedule and cost forecasting; and (3) an integrative method that maximizes the value of information – subjective or objective – available from standard construction project management practice. A numerical example is presented to show the adaptive nature of the new method along with the advantages of a probabilistic approach compared to deterministic methods. In the example, the Bayesian model averaging technique is used to combine predictions by different S-curve models and the results indicate that combined predictions outperform individual predictions.

Keywords: forecasting, project control, project management, scheduling, S-curves.

INTRODUCTION

Project engineers and managers are constantly seeking some indicators that will give them early warning of how well their projects are going based on the predicted cost and duration for completion of individual tasks and complete projects. Such predictions need to be revised and compared with the scheduled completion date and the available budget. The effectiveness of project controls relies on the capability of project managers to forecast final cost and completion time with acceptable accuracy and in a timely manner. One must make the best use of the information being generated by the project itself, in order to forecast its future. Now that most projects, and all major projects, are computerized, there arises the opportunity to make better use of the information being captured by these systems to forecast the future of the project.

Adequate methods to do this are lacking, because the existing methodologies for project performance forecasting, for example, the critical path method (CPM) and the earned value management system (EVM), are almost entirely deterministic and fail to

[1] man2020@tamu.edu

account for the inherent uncertainty in forecasting and project performance. Those methods do not provide confidence bounds on predictions, which are essential to efficient decision making under uncertainty. In addition, the traditional methods do not provide consistent frameworks for both schedule and cost forecasting, and are based on inconsistent assumptions on the relationship between past and future performance. For example, the EVM provides some simple rules for forecasting the estimated cost at completion (EAC) from the budget at completion (BAC) and the cost performance index (CPI), but these are typically linear extrapolations – assuming, for example, that the CPI, which has changed in the past (or it would always equal 1.00) will not change in the future. The CPM predicts the time at completion given a delay in some critical path activity, but typically assumes that delays that affected past activities will not affect future ones. Furthermore, EVM schedule forecasting formulas have been criticized for systematic distortion in the estimated duration at completion by researchers (Short 1993; Vandevoorde and Vanhoucke 2006) and practitioners (Lipke 2003; Leach 2005; Sparrow 2005). As a result, a common practice in the project management community is to use EVM for forecasting EAC and the CPM for managing schedule performance (Fleming and Koppelman 2006; Lipke 2006).

The Bayesian adaptive forecasting model proposed in this research is a probabilistic framework for forecasting project progress and posterior probability distributions on project duration and cost at completion. The ultimate goal of this new approach is to provide decision makers with objective and refined forecasts in a timely manner, which can be used to grasp the current performance more clearly, to forecast the future progress more reasonably and to identify potential measures to improve the chance of successful project completion. Bayesian inferencing, or the revision of beliefs about future activities based on the information gained about past activities, offers a number of opportunities for making more reliable forecasts of future outcomes – and for making reliable forecasts sooner, when they are more valuable to project management. In a general framework of Bayesian inference and forecasting, the proposed method combines all relevant information concerning future performance of an ongoing project, including prior subjective information, baseline progress and its associated uncertainty, and actual data on project progress. For example, Bayesian inference is used to permit prior subjective probability estimates to be combined with actual data on project progress to yield the best estimators of time and cost at completion. The final result is a set of probability distributions on project duration and cost at completion, which are updated as more progress data are reported.

It should be noted that the new method can be applied to forecasting cost performance as well as schedule performance of projects as long as the performance is measured in terms of cumulative progress metrics that show S-like patterns. However, this paper focuses on schedule performance forecasting. Application of the proposed method to cost predictions is straightforward.

EVM PERFORMANCE METRICS

The primary data that should be relied on for predicting future performance of a project are past performance data observed in the project. Recently, EVM has been recognized as a viable method for measuring and controlling project performance, and in use by many public agencies (its use is mandated by NASA, DoD, DOE, and others) and by private owners and contractors to evaluate complex projects. It has the advantage of being universally applicable over a wide range of project types and sizes, because every project, no matter how large or complex, is represented by the three functions: the planned value (PV or the budgeted cost of work scheduled), the earned value (EV or the budgeted cost of work performed), and the actual cost (AC or the actual cost of work performed). Graphical representations of these fundamental functions at time *t* are shown in Figure 1.

The Bayesian adaptive model uses the three performance variables in typical EVM as actual performance data. The project cost and duration at completion predicted at time *t* are updated in terms of the estimated cost at completion (EAC(*t*)) and the estimated duration at completion (EDAC(*t*)), respectively (Figure 1). It should be noted that since the new forecasting method uses the EVM metrics as the primary performance measures, it is focusing on the summary level project progress rather than individual work packages. Any type of progress measure can be used in the new method, not just the EVM metrics. However, we will use the EVM metrics to stand for any progress relation that is monotonically non-decreasing.

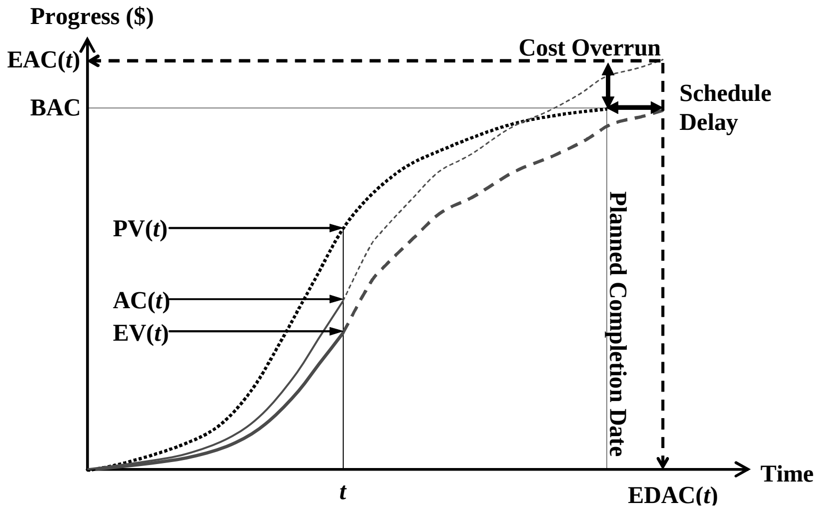

Figure 1: The earned value management metrics

BAYESIAN ADAPTIVE MODEL

Model outline

Bayesian adaptive forecasting (BAF) is a regression model that fits S-curves to actual progress data and updates the parameters of the S-curves using Bayesian inference. Bayesian inference is used to combine prior subjective information with actual data on project progress to yield more reliable estimates of project duration and cost at completion. The Bayesian forecasting approach starts from the premise that there exist typical progress patterns that represent the characteristics of individual projects, such as resource distribution over the project life cycle. The challenges in applying the Bayesian adaptive forecasting method are to identify the unknown actual progress pattern and to fit it to actual performance data available at the time of forecasting.

The outline of BAF is shown in Figure 2. The BAF consists of three procedures: model selection, parameter updating and forecasting. We first obtain from the project plan the prior progress curve, for example, the planned value distributed over time, as determined by the resource-loaded schedule for the project or task under consideration. Then we approximate this set of planned values by fitting some S-curve functions to the points. If the fit of the function to the planned progress is reasonably good, then we can use the function to represent the planned curve, and generate revised curves in the same family by varying the parameters (typically two or three).

What makes this model original is the use of multiple S-curves in project progress predictions combined with the Bayesian approach to updating probability distributions of model parameters. As a result, the prior progress curve can be defined in either a deterministic or a probabilistic way.

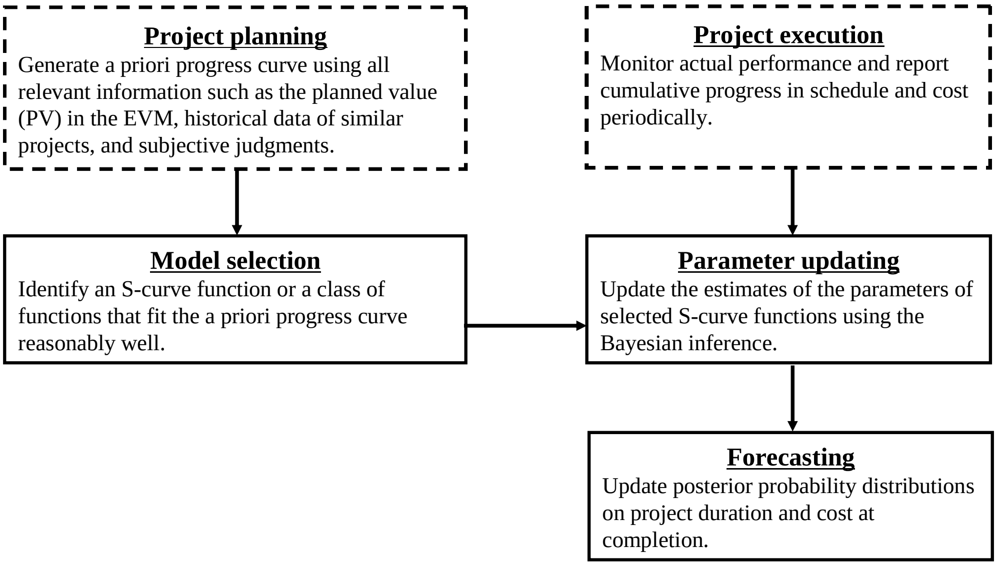

Figure 2: The outline of the Bayesian adaptive forecasting framework

S-curve progress models

An S-curve in project management is a cumulative progress curve that represents the amount of work done or to be done by a specific time throughout the execution phase. Typical cumulative progress curves of projects show S-like patterns, regardless of the unit of measurement, for example, cumulative costs, labour hours, or percentage of work (PMI 2004). The S-curve is a universal characteristic of all projects, regardless of the type, size and complexity of a project.

To generate an S-curve of a project, we need the project schedule and budget allocated to the activities. Then a point on the S-curve at a specific time is the amount of work to be done by that time. Many projects are actually managed by the S-curves. However, previous studies of the use of S-curves as a quantitative tool, not just a visual display, are very limited (Murmis 1997; Barraza *et al.* 2000, 2004; Cioffi 2005). Murmis (1997) generated a symmetric S-curve from a normal distribution and forced it to pass through fixed points of the cumulative progress curve. Murmis applied the curve to detect problems in project performance. A more flexible S-curve was presented by Cioffi (2005). He modified a typical sigmoid curve used frequently in ecology by imposing three project boundary conditions: zero-initial state, the slope of the rise in the S-curve, and the time at which half the total work has been completed. Barraza and his co-researchers (2000, 2004) tried to use a set of S-curves generated from a Monte Carlo simulation program as a visual project control tool. Useful as they are, these previous works are not applicable to the current research of forecasting at-completion project duration and cost of ongoing projects, largely because of poor flexibility of the suggested S-curves and the lack of forecasting algorithms based on actual performance information available at the time of forecasting.

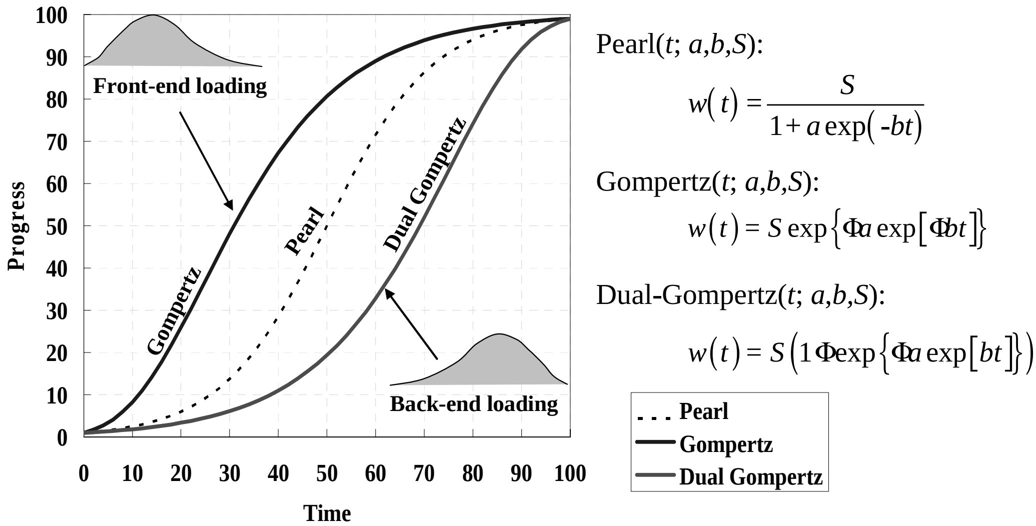
Experience has shown that most projects and project tasks follow sigmoidal patterns, but the individual shapes vary, and so no universal function has been yet found that fits all projects and tasks. Therefore, to apply this method of forecasting, it is necessary to have available a set of functional forms that can be trial-fitted to the dataset. Some basic S-curve models are shown in Figure 3. The Pearl and Gompertz belong to logistic functions that have many application areas in biology and economics. The Dual-Gompertz function is a modified form of the Gompertz to represent the progress of a project with back-end loading. As mentioned earlier, the accuracy and reliability of the BAF depend heavily on finding a mathematical function or functions that represent the planned progress reasonably well. Therefore, a reasonable way of improving the quality of predictions from the BAF is to start with many diverse S-curve functions and to screen them in an effective and systematic way. In an effort to enrich the library of mathematical S-curves, two original S-curve models, which are termed ‘Function 46’ and ‘Function 50’, were developed by the second author of this paper and successfully used in the numerical example in this paper.

Function46(t; n,b,S):

$$w(t) = S\left[\frac{b\,\Phi t}{b}\right]^{n+1}\left[\left(\frac{b\,\Phi t}{b}\right)(n+1)\,\Phi(n+2)\right] + S$$

Function50(t; n,b,S):

$$w(t) = S\left[\frac{(n+3)(n+2)(n+1)}{2b^2}\right]\left[\frac{b\,\Phi t}{b}\right]^{n+1}\left[\frac{2b(b\,\Phi t)}{n+2}\,\Phi\,\frac{(b\,\Phi t)^2}{n+3}\,\Phi\,\frac{b^2}{n+1}\right] + S$$



Pearl(t; a,b,S):

$$w(t) = \frac{S}{1 + a\exp(-bt)}$$

Gompertz(t; a,b,S):

$$w(t) = S\exp\left\{\Phi a\exp\left[\Phi bt\right]\right\}$$

Dual-Gompertz(t; a,b,S):

$$w(t) = S\left(1\,\Phi\exp\left\{\Phi a\exp\left[bt\right]\right\}\right)$$

Figure 3: Examples of S-curve functions when $w(0) = 1$, $w(100) = 99$, and $S = 100$

Updating model parameters using Bayesian inference

The parameters of an S-curve model are estimated and updated through Bayes’ law whenever new actual performance data become available. If a project manager has an initial estimate of project progress (that is, a project plan) and if this progress curve is fitted to some known model with associated parameters (ς), the belief in the individual model parameters can be updated with actual performance data (D) as the project proceeds. Bayes’ law for this case can be written as:

$$P(\varsigma \mid D) = \frac{P(D \mid \varsigma)P(\varsigma)}{P(D)} \tag{1}$$

where $P(\Theta)$ is the *prior distribution* reflecting the belief in parameters before observing new outcomes; $P(D|\Theta)$ is the *conditional probability* that the particular outcomes *D* would be observed, given the parameters Θ; $P(D)$ is the marginal distribution of the observables *D*; and $P(\Theta|D)$ is the *posterior distribution* of the parameters Θ given that the outcomes *D* were observed.

Formulation of the Bayesian adaptive forecasting model

For an S-curve function with *m* parameters, the Bayesian updating process proceeds as follows. Let Θ denote the set of parameters $\{\theta_1, \theta_2, ..., \theta_m\}$. We choose parameters independently so that the prior probability distribution of the parameter set is represented as

$$p(\Theta) = p(\theta_1)\, p(\theta_2) \cdots p(\theta_m) \tag{2}$$

Once a project gets started, actual progress is reported periodically and the data can be represented as a series of discrete values *D*.

$$D : (w_i, t_i),\ i = 1, ..., N \tag{3}$$

where w_i represents the cumulative progress reported at time t_i and *N* is the number of records up to the time of forecasting.

The likelihood of the data conditional on the parameters chosen is measured based on the errors between the actual times of performance reporting and the planned times determined by a specific S-curve model and the parameters, $T_M(w_i | \Theta)$. We seek an S-curve model and its associated parameters that make the errors normally distributed with zero mean and standard deviation σ. It is assumed that the random errors corresponding to different observations are uncorrelated. Then the likelihood of the data conditional on the parameters is calculated as the product of the likelihood of each observation.

$$p(D|\Theta) = \prod_{i=1}^{N} p(t_i, w_i | \Theta) = \prod_{i=1}^{N} \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{1}{2} \left(\frac{t_i - T_M(w_i | \Theta)}{\sigma} \right)^2 \right] \tag{4}$$

It should be noted that the value of σ is determined by decision makers or forecasters to adjust the sensitivity of predictions to the actual data reported.

The marginal distribution of the observables *D* is determined from

$$p(D) = \int p(D, \Theta)\, d\Theta \tag{5}$$

where the joint probability distribution of data and parameters is constructed from Equations 2 and 4 as $p(D, \Theta) = p(D|\Theta)\, p(\Theta)$.

The ultimate goal of the Bayesian approach to prediction problems is to obtain a posterior marginal distribution of each model parameter conditional on the observed data. Using fundamental properties of conditional distribution, the posterior marginal distribution of parameter θ_i can be derived by integrating the joint parameter distribution conditional on the observed data, which is determined from Equations 1 to 5, with respect to the remaining parameters ($\theta_1, \cdots, \theta_{i-1}, \theta_{i+1}, \cdots, \theta_m$).

In the Bayesian adaptive forecasting framework, *a priori* information from various sources is taken into account in terms of prior distributions of model parameters. Table 1 summarizes some examples of additional performance information that can be used as inputs.

Table 1: Additional information used in the Bayesian adaptive forecasting method

Types	Descriptions
Project activity network **G** = G(*n*, *r*)	A project activity network is represented as a directed acyclic network G(*n*, *r*), where *n* is the number of activities in the network and *r* is the number of Finish-to-Start relations among the activities.
Activity durations and costs **A** = {a_1, a_2, …, a_n}	Each element of the information set, **A**, has probabilistic estimates of an activity duration and cost.
Historical progress information **H** = {h_1, h_2, …, h_m}	A historical dataset might be represented as a series of discrete performance indicators. *m* is the number of historical progress datasets.
Subjective information **S** = {c_1, c_2, …, c_s}	*s* is the number of subjective information sets that can be chosen by decision makers. In the proposed methodology, a subjective information set is represented in terms of numerical constraints for the model parameters.

NUMERICAL EXAMPLE

An artificial project has been analysed to demonstrate the performance of the new Bayesian adaptive forecasting model. First, a random activity network of a project with 200 activities and 279 precedence relations is generated using a random network generation method augmented with a redundancy elimination technique. Then, Monte Carlo simulation is carried out to determine the planned progress curve and the prior probability distribution of the completion date. The completion dates and corresponding progress curves for a set of random activity durations are calculated with the early start forward calculation in CPM. It is assumed that all activities in the project are homogeneous with the same stochastic properties in duration and cost. This homogeneous assumption is based on a scheduling practice in which activities in a project network are defined in such a way that they are just small enough to be managed effectively, and not too small to cause additional burdens in management.

The planned progress and the simulated ‘actual’ progress used in the numerical example are shown in Figure 4. From a Monte Carlo simulation based on a random activity network and the assumed probability distributions of activity durations and costs, the prior distribution of the completion date is estimated to have the mean of 71 weeks and the standard deviation of 6.6 weeks. The planned progress curve in Figure 4 is determined by averaging stochastic progress curves from 5000 iterations over the progress dimension. The dotted line represents a simulated progress curve with completion date at 79 weeks. The simulated curve is generated from the same network schedule for the planned progress curve. Therefore, the curve represents an ‘actual’ progress of the project, which is determined at random owing to the uncertainty in the assumed activity durations and costs. It should be noted that, although the complete actual progress is determined in advance, the actual performance data are assumed to be available only after each reporting period up to the time of forecasting.

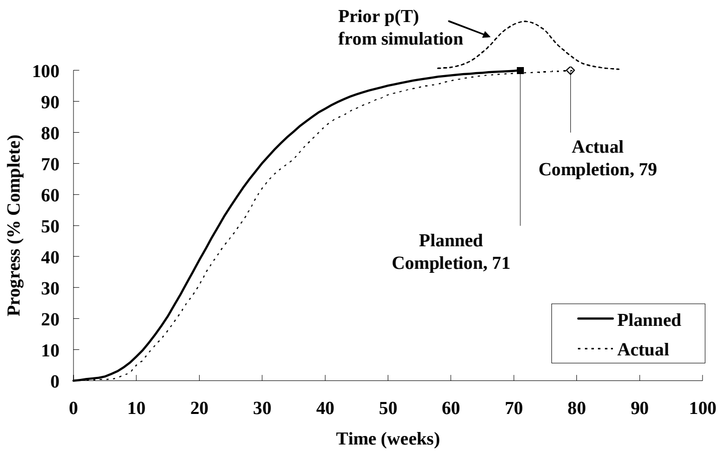


Figure 4: The simulated 'actual' progress curve and prior information from a random activity network, **G**(200,279), and the assumed activity information, **A** = $\{a_1,\ldots,a_{200}\}$

The five S-curve functions discussed earlier are fitted to the planned progress curve. The least squares method is used to measure the goodness of fit and four functions other than the Dual-Gompertz function fit the planned progress curve reasonably well. The fitted graphs are shown in Figure 5 and the corresponding prior estimates of the model parameters are shown in Table 2. It should be noted that the prior distribution of the completion date, which is obtained from the network-based schedule simulation, is also taken into account in terms of a random variable T in the formulas for slope parameter b. The results show that the Gompertz function best fits the current planned progress with the minimum sum of the squares of vertical deviations.

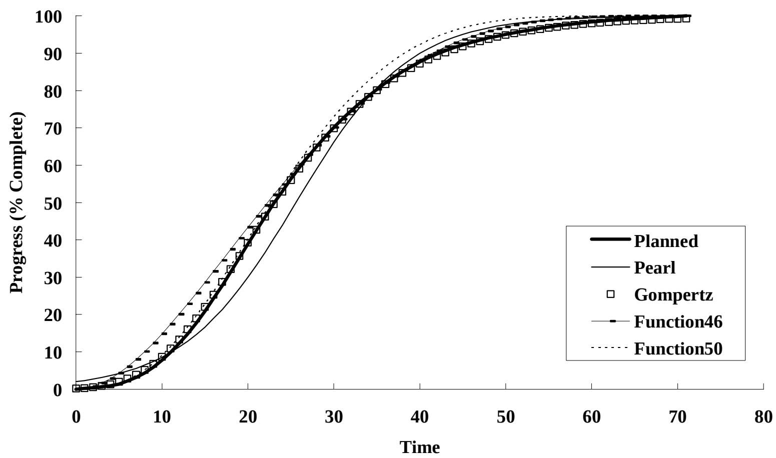

Figure 5: S-curve functions fitted to the planned progress

Table 2: Prior estimates of model parameters

	Parameters for shift (*a*) or shape (*n*)	**Slope parameter (*b*)**	**Sum of the squares of vertical deviations**
Pearl	a = 49.0	$[\ln(49) - \ln(1/49)]/T$	1102
Gompertz	a = 6.377	$[\ln(6.337) - \ln(0.00702)]/T$	23
Function46	n = 3	T	765
Function50	n = 5	T	520

With the prior estimates of model parameters and weekly performance reports, EDAC is calculated after 10, 20, 30 and 40 weeks using the four S-curve functions. The results are shown in Figure 6. Different predictions from different models are combined with weights according to the relative reliability of the models, which is determined as the marginal probability of observing actual performance data conditional on each model. The predictions at week 10 show that all models provide similar results that are close to the prior estimates of completion date. This is attributed to the fact that the Bayesian adaptive model uses both prior information and actual progress data, and the prediction is influenced more by the plan than it is by the small number of data points reported up to this time.

The other three graphs in Figure 6 show the adaptive nature of the BAF. Undoubtedly the forecast would be repeated after every reporting period to incorporate the new data, but here the intermediate updates have been omitted. Comparing the forecasts at different points of project execution, it is easy to see that each model responds to the actual performance data in a different way. After 20 weeks, predictions by Gompertz (M2), Function46 (M3), and Function50 (M4) move away from the plan and approach the actual completion date, due to the accumulated discrepancies between the actual reports and the planned progress curve. However, it should be noted that the planned completion date is still inside of the confidence bounds that are determined at two standard deviations above and below the expected EDAC. The confidence bounds should be determined in advance by project managers as a level of risk accepted by the owner or organization. As more actual data accrue, the confidence bounds on the predicted values become narrower for all models. After 30 weeks, the combined prediction gets closer to the actual completion date, and more importantly, the confidence bounds indicate that the probability of completing the project within the planned completion date becomes lower than the predetermined acceptable level. Predictions after 40 weeks clearly show these patterns and the combined forecast provides more accurate prediction of the actual completion date than its component forecasts.

CONCLUSIONS

The new Bayesian adaptive forecasting model provides informative and reliable predictions on project duration and cost at completion because it provides confidence bounds on predicted values and *a priori* information and uncertainties in typical construction projects are seamlessly integrated into consistent predictions. For example, a range estimate of project duration before the beginning of a project can be taken into the forecasting process and used to improve the reliability of predictions during the early phase of execution period when project managers often suffer from lack of actual performance data to make decisions about taking controlling actions.

In addition, easy implementation to real projects will make the new method attractive aids for better project schedule and cost management practices. Any projects whose performance is monitored and managed using the EVM can adapt the new methods with almost negligible efforts and cost. The Bayesian adaptive forecasting model is developed as a spreadsheet program such as Excel® and can be easily integrated into the typical earned value management system.

USING COGNITIVE MAPS FOR RISK MODELLING IN CONSTRUCTION PROJECTS

Irem Dikmen[1], M. Talat Birgonul and Guzide Atasoy

Civil Engineering Department, Middle East Technical University, Balgat, Ankara 06531, Turkey

Successful management of risk requires identification of risk sources, construction of risk models and preparation of management plans throughout the life cycle of a project so that the project objectives can be met. Risk modelling is a critical step in the risk management process as a risk model is used to simulate the project performance under different scenarios and it constitutes the foundation of a risk management plan. In this paper, major challenges of developing realistic risk models in construction projects are discussed. One of the problems is inconsistent definition of risk sources, consequences and factors that affect the impact of risks on project success. Although some of the individual risk factors may be more significant than the others are, the project success usually depends on the combination of all risks, response strategies used to mitigate risks and a company's ability to manage them. Thus, there exists a need to develop a risk model that contains the interrelations between risks, response strategies and project success criteria. A cognitive map is a qualitative model of how a system operates under different conditions where the conditions are simulated by different values of variables that can be physical quantities or abstract concepts and the causal relationships between them. The potential applications in the risk management domain are basically, risk assessment for the prediction of project success and risk evaluation during post-project appraisal. It is also possible to use cognitive maps for comparison purposes. In this paper, development of risk models with cognitive maps is demonstrated on a real project. The example project is a major highway project amounting to approximately 600 million US dollars carried out by an international joint venture. The cognitive map of a person at the top management level is drawn to model the risk sources, consequences, strategies and project success criteria. Case study findings demonstrate that cognitive mapping may be used as an effective learning tool for risk evaluation.

Keywords: cognitive maps, post-project appraisal, risk.

INTRODUCTION

Risk management (RM) is a formal process for systematically identifying, analysing and responding to risk events throughout the life of a project to obtain the optimum or acceptable degree of risk elimination or control. RM is about definition of objective functions to represent the expected outcomes of a project, measuring the probability of achieving objectives by generating different risk occurrence scenarios and development of risk response strategies to ensure meeting/exceeding the preset objectives (Dikmen *et al*. 2004). RM in construction is a tedious task as the objective functions tend to change during the project life cycle, and the risk scenarios are numerous due to sensitivity of construction projects to uncontrollable risks stemming from the macro-environment, existence of high number of parties involved in the project value chain, and one-off nature of the construction process (Jaafari 2001). In this paper, challenges of risk

[1] idikmen@metu.edu.tr

modelling are discussed and potential usage of cognitive maps is proposed to eliminate some of these challenges.

RISK MANAGEMENT: CHALLENGES

In order to handle the complexities of the risk management process in construction projects, a formal risk management system is necessary. The tools, techniques and information requirements of risk management process shall be defined as a part of the risk management system that has basically three outputs:

- Risk register: it is a risk checklist in which the risk sources are defined together with their expected impacts and probabilities.
- Risk model: it is used to simulate the project performance under different scenarios (in the presence of the identified risk factors).
- Risk management plan: it is an action plan, based on the risk register and risk model, where effective strategies are generated to manage risks.

The success of a risk management plan is dependent on how the risks are identified and modelled. When the literature is investigated, it is clear that there are numerous risk checklists and risk breakdown structures proposed by different researchers. The major drawback in some of these lists is “inconsistency”. The word risk may be used to imply source, consequence or probability of occurrence of a negative event. When risk sources are mixed with consequences, this leads to a major inconsistency and wrong formulation of the risk model. For example, a consequence like cost overrun should be considered on a different platform than sources such as inflation, technical risk or changes in project scope. Another problem is the interdependency between the risk sources. The most widely used risk rating technique based on multiplication of probability with impact is an over-simplistic approach as it is based on the assumption that “risk factors are independent”. There are usually correlations between risks as they may be affected from similar underlying sources. Moreover, in the assignment of ratings (usually using Likert scale), there may be significant differences between the values attached by decision-makers due to different assumptions about “level of controllability”. Some people may consider that the probability of occurrence of a risk factor is low if it is controllable by assuming that necessary precautions will be taken to eliminate them; while others may consider probability of occurrence regardless of response. Thus, some factors that affect the “magnitude of risk” shall be defined explicitly and the interrelations between these factors and risk sources shall be defined clearly.

Another problem related with the risk management process is that risk management plans are usually prepared at the start of the project, usually not revised during the life cycle of the project and not evaluated at the end. The aim of RM should be effective monitoring of risks and project success in order to revise plans, better communication of risk between project participants, construction of a corporate memory to introduce experience-based solutions of how risks can be avoided and, finally, learning from risks. In order to facilitate learning from the actually happened risk events, risk management plans shall be compared with the actual risk consequences and effectiveness of risk management plans shall be evaluated as a part of post-project appraisal. If this comparison can be carried out successfully, lessons learnt about risks may be used as a valuable input for risk management efforts in the forthcoming projects.

Finally, it is a well-known fact that lack of common understanding of the parties about risk sources, response strategies and ownership may affect project success negatively. One of the aims of preparing risk management plans is to increase awareness of project participants about the risk scenarios and risk allocation schemes. The first step to eliminate potential conflicts between the project participants is identification of possible differences in their understanding of the project risk environment. If differences can be revealed at early stages of a project, the probability of having problems due to vagueness in risk allocation schemes can be minimized.

The aim of this paper is to discuss potential usage of cognitive maps (CM) to eliminate some of the above-discussed shortcomings. Cognitive maps may be used to construct better risk models, facilitate learning from risks and reveal differences in mental risk models of different parties.

COGNITIVE MAPS

CMs provide a holistic picture of an individual's overall perspective, without any loss of detail, enabling a decision-maker to move beyond the assumption of internal consistency to the detailed assessment of specific concepts within the map (Clarke and Mackaness 2001). A CM has the ability to reveal an actor's subjective understanding of the dynamics of socially constructed situations. It is a representation of the thoughts and knowledge of people with the usage of diagrams composed of concepts and their relations. The concepts are shown with nodes and the relations between the concepts are represented by arrows showing the direction and sign of causality. If the interrelations between nodes are shown by positive and negative numbers indicating the sign and strength of a relationship, these maps are called as weighted cognitive maps. Kosko (1986) introduced the concept of fuzzy cognitive maps (FCM), which are weighted cognitive maps with fuzzy link values.

CM was first introduced by Axelrod (1976) for political analysis and decision making. It has been used widely by researchers in a variety of different contexts such as management and administrative sciences (Eden 1992; Eden *et al*.1992; Langfield-Smith and Wirth 1992; Smith *et al*. 1995). Recently, CMs have been used in modelling the strategy building process (Carlsson and Fuller 1996), the process of way finding (Chen and Stanney 1999), business redesign (Kwanhk and Kim 1999) knowledge management (Noh *et al*. 2000), design of electronic commerce websites (Lee and Lee 2003) and modelling IT projects success (Rodriguez-Repiso *et al*. 2007). In the construction management literature, there are only a limited number of studies that use the influence diagramming method, which is a special form of cognitive mapping. Influence diagrams have been used by Ashley and Bonner (1987) for political risk assessment; by Poh and Tah (2006) for cost-time integration and by Dikmen *et al*. (2007) for risk modelling of international construction projects.

CMs can be used to deal with complex issues that can hardly be modelled with quantitative reasoning. Eden (2004) suggests the use of CMs to depict and explore the cognitive structures of members of organizations who are facing complex issues. CMs may also be used to acknowledge differences in management views and encourages discussion, suggesting alternative courses of action. Using case studies about IT/IS, Al-Shehab *et al*. (2004) argue that causal mapping may be used as an effective method of documenting past experience. They conducted an exploratory experiment using causal mapping method and reported that CM encourages participation and facilitates group discussions; enhances communication between group members; provides a clear picture of the situation through its diagrammatic representation; and, finally, enables the identification of interrelations between several factors (such as risk, decisions, assumptions etc.).

Its benefits such as drawing a holistic picture of an individual's overall perspective, reflection of managerial perceptions of real world and providing a platform for comparison of different mental models make it an appropriate tool to eliminate some of the above-discussed shortcomings of RM. In the next section, potential uses of CMs for RM will be discussed.

POTENTIAL USES OF COGNITIVE MAPS FOR RISK MANAGEMENT

CMs can mainly be used for construction of individual mental risk models, comparison of risk models drawn by different decision-makers, prediction of risk impacts and learning from previous projects.

As risk modelling necessitates consideration of risk sources, consequences and influencing factors, CMs can be used effectively to demonstrate the causal relations between the concepts. Influence, causality and system dynamics of a project's risk environment can be modelled and a holistic picture of an individual's overall risk perspective can be drawn. CMs can be used either for risk modelling at the start of a project or after project completion. Risk events may be evaluated at the end of a project in order to increase learning from what actually happened in the project. Risk evaluation process can be facilitated by CMs, which can effectively summarize a complex network of variables.

For revealing understanding of concepts related with risk, a CM can be drawn by each project participant. The cross-sectional differences between groups of actors may be revealed and if the differences are due to misunderstanding, wrong assumptions and vagueness of some concepts, they may be tried to be eliminated for a common understanding of the risky situation. CMs drawn before and after the project may be compared to monitor how belief systems change over time. The study of past projects can help to sensitize project participants to the potential problems that may affect the new project's success. Thus, CMs may facilitate learning in an organization.

FCMs (Kosko 1986) can be used to analyse, simulate, test the influence of parameters and predict the behaviour of a system. FCM is a supervised learning neural system that can produce responses from a given set of initial conditions. Thus, if a set of actually happened risk cases are fed into a CM together with their actual outputs, it may learn the relations between the concepts and may predict an output when it is given a set of input conditions such as magnitude of risks, planned strategies, contract conditions etc. The difficulty lies in the fact that as the construction projects as well as the conditions under which they are realized are unique, it is hard to collect enough data about similar cases. If the number of cases is low, FCM may not be able to learn the magnitude of interrelations between the concepts and its prediction ability may be low.

Cognitive maps are usually derived through interviews and so they are intended to represent the subjective world of the interviewee (Eden 2004). Systematic approaches exist for elicitation and comparison of CMs; particularly tools such as Cognizer and Decision Explorer can be used to explore the structure and content of CMs and make comparisons between different maps. In the next section, the utilization of cognitive mapping method for risk evaluation in a construction project is demonstrated by a case study.

AN APPLICATION OF COGNITIVE MAPS TO A HIGHWAY PROJECT

The case study project is a major highway project that includes the construction of two tunnels, four viaducts, three bridges, one overpass and two subways. The project is carried out by an international joint venture (Italian and Turkish contractors) responsible from engineering, design and construction. The contract was signed in 1990 and construction started on 1993. The duration of the project was planned to be 48 months and its estimated cost was around 570 million US $. Actually, it was completed approximately in 14 years (partially opened on January 2007) and costed around 1 billion US $. There was a big public reaction due to the delays and cost overruns of this mega project. The reasons of failure to keep up with time and budget limits are announced to be *force majeure* events (mainly earthquake) and extensive design changes. In this paper, factors that affected the project success will be discussed by referring to the CM of a manager who works in the Italian construction company. The map reflects his perceptions and cannot be interpreted as an objective model of the drivers of success/failure in the case study project.

The CM was drawn as a result of an interview that took around two hours. The interviewee was allowed to talk about the factors that affected the success of the highway project. Every concept he mentioned was written on a piece of paper; at the end of the session, these concepts were shown to him. The majority of the concepts that he identified were problems (risk events, wrong decisions etc.) rather than fortunate events that affected the success of the project. After validation of the completeness of the list of concepts, a preliminary cognitive map was drawn up by the researchers, according to the information gathered during the interview, which was submitted to the interviewee together with an empty adjacency matrix. The adjacency matrix shows the strength of the causal relations between the concepts. The interviewee was requested to check the structure of the cognitive map and fill the necessary values in the adjacency matrix using the given evaluation scale (see Table 1).

Table 1: Evaluation scale

Value	Explanation
1	Very high positive impact
0.8	High positive impact
0.6	Moderate positive impact
0.4	Weak positive impact
0.2	Very weak positive impact
0	No relation
-0.2	Very weak negative impact
-0.4	Weak negative impact
-0.6	Moderate negative impact
-0.8	High negative impact
-1	Very high negative impact

The final list of concepts is presented in Table 2. After the interviewee validated the structure and assigned the link values, the CM was finalized. The final version of the CM for the case study project and adjacency matrix are presented in Figure 1 and Figure 2, respectively.

Table 2: List of concepts

Concept ID	Description
C1	Poor performance of the engineer
C2	Errors in specifications
C3	Political interference/pressure
C4	Economic crisis
C5	Poor geotechnical investigation
C6	Flood
C7	Earthquake
C8	Design changes
C9	New local partner
C10	Suspension of works
C11	Change in the management team
C12	Change orders by the client
C13	Bureaucratic delays
C14	Conflict with partners
C15	Wrong decisions about project management
C16	Poor performance of the subcontractor
C17	Low productivity
C18	Change in scope
C19	Wrong construction method/technology selection
C20	Increase in the amount of work
C21	Delay
C22	Increase in costs
C23	Claims/disputes with the client
C24	Risk adjusted bid price/appropriate contingency
C25	Profitability
C26	Public pressure
C27	Poor reputation
C28	Project success

Figure 2: Adjacency matrix

DISCUSSION OF FINDINGS

There are a variety of methods for exploring cognitive maps. CMs are usually analysed in terms of their content and complexity. As CMs can be complex, graph theory indices provide a way to analyse their structures (Eden *et al*. 1992). In the CM of the case study, there are 28 concepts (Table 2) and 46 links. The complexity value as a network is 1.6, which is the ratio of links to concepts. As this number gets higher, the complexity of the map tends to increase. The most important factors as defined by the interviewee within the CM can be identified by calculating centrality values of the concepts. Centrality of a variable is the summation of its indegree and outdegree values (Ozesmi and Ozesmi 2003). The indegree value reveals the extent to which a concept is influenced by other concepts (column sum of the absolute values of a variable in the adjacency matrix) whereas outdegree value shows the cumulative strength of variables exiting the variable (row sum of the absolute values of a variable in the adjacency matrix). Transmitter variables have a positive outdegree and zero indegree whereas receiver variables have a zero outdegree and a positive indegree. Ordinary variables have both positive outdegree and indegree values (Eden *et al*. 1992). In the case study, the variables that have the highest outdegree values are "increase in cost", "delay" and "engineer" meaning that those variables significantly affect other variables. "Change in scope", "increase in the amount of work" and "delay" have the highest indegree value implying that these variables are significantly affected from others. It is understood from the CM that, the project success is significantly affected from risk events (such as economic risk, earthquake etc.) but the effects of these risks are first reflected to variables such as "productivity" and "delay". As well as the risk factors, there are certain variables like "wrong decisions" and "contingency in the bid price" that influence the consequence variables together with the risk factors. Majority of the 10 transmitter variables are risk factors (such as economic crises, earthquake etc.) and given conditions (poor geotechnical conditions, wrong selection of the construction method). The 13 ordinary variables (such as productivity) carry the impact of risks and given conditions to the forthcoming variables (such as delay). The centrality values of variables "design changes", "change in scope" and "increase in costs" are the highest among all concepts implying that they influence and influenced by many factors. It is clear that rather than listing a couple of reasons of success/failure, drawing a CM that explains the chain reactions between risk events, conditions, consequences and project success criteria is a better way of presenting the lessons learnt in a project. Particularly in this project, the project success seems to be negatively affected from the poor reputation of the company which is developed as a result of significant delays and poor profitability due to increase in the amount of works as a result of change orders by the client and scope changes due to unanticipated events like earthquake and flood. However, wrong decisions about project management and conflict between partners also significantly affected the project success and company may learn from these mistakes. Risk adjusted bid prices influences profitability in a positive way meaning that the company was successful in choosing the contingency percentage in this project, which is also a valuable piece of information for the forthcoming projects.

CONCLUSIONS

Although risk checklists are widely used in construction projects, their reliability is questionable as many risk factors are interrelated and there are some influencing factors that should be considered during risk assessment. Cognitive mapping is proposed as an alternative method in which the complex relations between risks and other factors may be effectively modelled. CMs may be used for risk identification at the start of a project so that the risk information can be communicated effectively and risk evaluation during post-project appraisal so as to facilitate organizational learning. In addition, CMs of different project participants may be drawn and compared to reveal potential areas of similarity and/or conflict. The case study findings demonstrate that lessons learnt in a project can be diagrammatically represented and may form an appropriate platform for discussing the sources and impacts of risks together with influencing factors. The CM can be interpreted using indices, which may provide summary information about a complex situation. Major advantages of using cognitive mapping are identified by the interviewee as visualization of the project environment, particularly chains of events that lead to success/failure and documentation of lessons learnt. The major drawback as specified by the interviewer is the complexity of the diagram. The size of the map should be tried to be minimized so that it may be easy to analyse and comprehend.

Finally, CMs are criticized as they may reflect the biases and misconceptions of participants. Actually, it may turn out to be an advantage if the aim is to reveal the similarities and dissimilarities between the mental models of participants. Although CMs may not be directly used as objective tools for risk quantification, they may provide valuable information about a network of variables and concepts within a project setting.

PREDICTING THE OPERATION AND MAINTENANCE COSTS OF APARTMENT BUILDINGS AT PRELIMINARY DESIGN STAGE: COMPARING STATISTICAL REGRESSION AND ARTIFICIAL NEURAL NETWORK METHODS

Kung-Jen Tu,[1] Yuan-Wei Huang,[1] Chao-Ling Lu[2] and Kuo-Hui Chu[3]

In Taiwan, public facilities of many apartment buildings often became obsolete because their operation and maintenance (O&M) costs were too high for residents to afford. Since the design decisions at preliminary design stage would greatly affect a building's O&M cost during occupancy stage, the possibility of public facility obsolescence can be greatly reduced if accurate O&M costs prediction models to be used at preliminary design stage are developed. The objectives of this research are to employ statistical regression and artificial neural network (ANN) methods to develop two O&M prediction cost models used at preliminary design stage of apartment building projects, as well as to compare the predictive capability and accuracy of both models. Six design attributes were identified as critical factors to be considered at preliminary design stage as well as the inputs of both cost prediction models: building age, number of apartment units, number of floors, average sale price, total floor area, and public facility floor area. Sixty-five apartment buildings in Taipei City and Taipei County were identified as the subjects of this research, and data related to the six design attributes and O&M cost were collected. Data of 55 apartment buildings were used to develop the regression model and ANN model, and those of the remaining 10 apartment buildings were used to compare the performance of both models. The study revealed that the ANN model is a more accurate and stable cost prediction model (with a maximum error around 15%) as compared with the regression model.

Keywords: artificial neural network, cost modelling, maintenance, regression analysis.

INTRODUCTION

Background

In the development and design of apartment buildings in Taiwan, there has developed a trend that higher percentages of floor areas, as high as 35% of total floor areas (Chen and Chen 1999), are allocated for public facilities, such as lobby, service core, equipment rooms, guardrooms, central monitoring rooms, conference rooms, audio-video rooms, swimming pools, gyms, libraries, and so on, to fully meet residents' functional and recreational needs in their daily lives. However, a domestic study and

[1] kjtu@mail.ntust.edu.tw

investigation revealed that many public facilities of such apartment buildings have become obsolete because the operation and maintenance costs of these apartment buildings were too high for their residents to afford (Chen and Chen 1999).

Since high percentages of building operation costs were determined by programming decisions and building specifications in early design phases (Bogenstätter 2000), it is imperative to develop accurate O&M cost prediction methods that can be used at preliminary design stage. With accurate O&M cost prediction methods, housing developers and architects can make better development and design decisions about the types and scales of public facilities of apartment buildings at early design stage by being informed of their predicted O&M costs. With the mechanism to ensure that the O&M costs to be shared by the residents are affordable, the possibility of public facilities obsolescence in apartment buildings can thus be greatly reduced.

Literature review: existing prediction models in the building construction field

A review of existing literature was conducted to realize the status of research works related to the prediction of operation and maintenance costs or life cycle costs in the building construction field. It was found that there has been a lack of development of prediction models to estimate buildings' O&M costs at preliminary design stage.

However, some research efforts dealing with other aspects of O&M costs or life cycle costs have been observed. For examples, Kirkham *et al*. (2002) demonstrated a methodology for modelling accurately the underlying 'probability distributions' of facility management costs in acute care hospital buildings in England and Wales, distributions that can be used in subsequent whole life cycle costing analysis. By compiling historical data of life cycle costs of hundreds of buildings, Bogenstätter (2000) calculated the 'characteristic values' of life cycle costs (average costs per square metre of gross floor area and variations represented in percentages) for each type of building, with the intention to provide architects and engineers with historical cost data and distributions information in early design stage so that the life cycle costs of the development building projects can be optimized strategically. Besides, Minami (2004) conducted a survey on a large number of post office buildings in Japan to investigate the patterns and trends of their annual repair and improvement work costs. None of these research efforts came up with prediction models that can be used in early design stage to predict the future O&M costs of buildings.

In addition, this research has uncovered a number of prediction methods that have been used for other purposes in the building construction field. For example, regression analysis was used to estimate the life cycle maintenance costs of hydraulic construction excavators over their useful lives (Edwards *et al.* 2000; Edwards and Holt 2001). In fact, existing literature in other research fields abounds with examples of the application of statistical regression methods to cost modelling. It is logical to consider statistical regression analysis as a potential candidate to model and predict O&M costs of apartment buildings at preliminary design stage.

It's also found that artificial neural network (ANN) has been used to predict building construction costs or certain performance aspects in the building construction field. For examples, ANN was used in early design phase to estimate the square metre cost of RC structural systems of residential buildings in Turkey (Günaydın and Doğan 2004). ANN cost model was developed to predict the total construction costs of building projects (Emsley *et al*. 2002; Kim *et al*. 2004). To ensure design-build project success, key variables that affect project performance were identified, and ANN technique was employed to predict the performance (cost, time, quality and client satisfaction) of design-build projects in Singapore (Ling and Liu 2004).

Artificial neural network (ANN) is a mathematical informational processing model that can learn from past examples or training data (Taylor 1996). Not only has it been used to perform classification, clustering and control tasks, but it has also been successfully applied to function approximation (Hill *et al*. 1994). Several distinguishing features of ANN make it valuable and attractive for a forecasting task: ANN is a data-driven self-adaptive method with the ability to learn from past experience; it can generalize what's learned from data and infer the unseen part of a population correctly; it can approximate any continuous function to any desired accuracy; and it is capable of performing non-linear modelling without *a priori* knowledge about the relationships between input and output variables (Zhang *et al*. 1998). ANN appears to be a more general and flexible modelling tool for forecasting, and has been applied to forecast non-linear time series, such as stock prices (Kohzadi *et al*. 1996), foreign exchange rate (Hann and Steurer 1996), electric load consumption (Srinivasan *et al*. 1994), and so on, with high accuracy.

Compared to the traditional model-based forecasting methods requiring assumptions about the underlying relationship between the input and output variables, ANN appears to be a promising method of O&M cost prediction for apartment buildings in early design stage, and a good candidate as an alternative modelling method to the classical regression analysis.

Research objectives

This research intends to develop accurate O&M cost prediction methods that can be used at the preliminary design stage of apartment building projects. The regression analysis and ANN were chosen by this research to establish two O&M cost prediction models for apartment buildings. To be more specific, the objectives of this research are: (1) to develop the regression model for O&M cost prediction; (2) to establish the artificial neural network (ANN) model for O&M cost prediction; and (3) to compare the predictive capability and accuracy of both models.

THEORETICAL FRAMEWORK

Key elements of O&M cost prediction models

The major role of the proposed O&M cost prediction models is to allow housing developers and architects to predict and estimate the future O&M costs of their proposed design schemes at preliminary design stages of apartment building projects. Through numerous rounds of O&M cost evaluations on proposed schemes at preliminary design stage, optimal design decisions regarding apartment buildings and public facilities can be made, future O&M costs to be shared by residents can be ensured to be affordable, and the possibility of public facility obsolescence can be minimized.

The proposed regression and ANN models will take building design attributes at preliminary stage as inputs to predict the building O&M cost as the output. To meet the specific needs of developers and designers in making design decisions at the preliminary design stage, it's argued that the proposed O&M cost prediction models should consist of the following four key elements:

1. *Meaningful building design attributes as the inputs to the proposed models*: the design attributes identified must be those typically known at preliminary design stage, and must be meaningful to housing developers and architects.
2. *Useful O&M cost factors as the outputs of the proposed models*: the O&M cost factors should be in a form useful to housing developers and architects in different contexts, and should provide the most flexibility so that different schemes can be applied subsequently.
3. *A representative sampling dataset based on previously analysed apartment building subjects*: the sampling data must represent a wide range of apartment buildings and contain many complete input samples of building design attribute data and corresponding outputs of O&M cost factors.
4. *Accurate and responsive O&M cost prediction models*: the structure of the proposed O&M cost models must be validated to ensure predictive accuracy. The proposed models should be easy to use and be responsive in providing O&M cost prediction results so that housing developers and architects can make fast comparisons of cost performance of different design schemes.

Operation and maintenance cost factors

In Taiwan, the costs to operate and maintain the public areas and facilities in apartment buildings generally consist of four parts: service cost (administration, security, cleaning); energy consumption cost (water, electricity); maintenance cost (mechanical equipment and landscape); as well as refurbishment and repair cost (interior remodel, structure and mechanical equipment repair). The O&M costs are typically shared by residents, in proportion to the area of their apartment units.

The first issue is to identify feasible O&M cost factors as the outputs of the regression and ANN models. After considering the requirements for O&M cost factors stated above, the following cost factor was identified as the output of the proposed model:

- Average monthly O&M cost: the annual total building O&M cost of an apartment building divided by 12 (NTD/month).

Apartment building design attributes

Building design attributes as the inputs to the proposed models need to be logically and statistically linked to the O&M cost, and to be readily available at preliminary stage. The design attributes must be able to discriminate between different concepts and be compact so that the demands on learning O&M cost model are reasonable. Finally, they must be easily understood by housing developers and architects. With these goals in mind, the existing literature was reviewed and experts were consulted to identify critical building design attributes.

Chen and Chen (1999) found that older apartment buildings in Taiwan incurred higher refurbishment costs, and larger and taller buildings incurred higher O&M costs. These findings suggest that building age, the number of apartment units or total floor area, and the number of floors of an apartment building may be related to its O&M cost.

Six experts experienced in developing, designing and managing apartment buildings were interviewed, and an open-ended question, i.e. 'what design decisions at building preliminary design phase may affect its future O&M cost?', was asked. Content analysis on experts' responses was then conducted. As a result, additional factors that may affect a building's O&M costs, such as the grade of apartment buildings, and the size or the diversity of public facilities, were identified.

As a result, the following six building design attributes were identified and their effects on O&M cost are speculated:

1. *Building age (year)*: the number of years between the year the building was registered and 2005. It is believed that the older the building, the more facility problems it has, and the higher its O&M cost.
2. *Number of apartment units (unit)*: the total number of apartment units in the apartment buildings with the same building registration number. It is speculated that the more apartment units, the greater number of residents, the heavier the public facilities consumed, and the higher its O&M cost.
3. *Number of floors (floor)*: total number of floors (including basement floors) of the apartment buildings with the same building registration number. It is supposed that the taller the building, the more complicated and sophisticated mechanical systems it is equipped with, and the higher its O&M cost.
4. *Average sale price (NTD/ping[1])*: the average price of apartment units purchased by residents at the time of building registration. It is suggested that the higher the sale price, the higher is the quality of public facilities demanded and provided, and the higher the cost required to operate and maintain the building.
5. *Total floor area (ping)*: total floor area (including basement floors) of the apartment buildings with the same building registration number. It is conjectured that the larger the total floor area, the larger the floor area of public facilities to be maintained, and the higher the building O&M cost.
6. *Public floor area (ping)*: total floor area designated as public facilities or uses in the apartment buildings with the same building registration number. It is logical to assume that the greater the public floor area in an apartment building, the more O&M work needs to be done, and the higher the building O&M cost.

RESEARCH METHODS

Data collection

This research randomly selected 200 apartment building communities from a population of 6682 communities whose commissions have officially been registered in Taipei City and Taipei County. After contacting the commissions of the 200 communities, 65 of them agreed to participate in this research and were identified as the subjects of this study. All 65 apartment buildings are private residential communities consisting of individually owned condominiums, most of which are occupied by owners and a small portion by tenants. Data related to the six design variables and the O&M cost of each apartment building community were collected by interviewing the members of its commission between August and November 2005. Structured questions regarding the annual total O&M cost and the six design attributes, as well as open-ended questions regarding the operation and management system (how the commission is organized, how the building is operated and managed, how the O&M cost is shared by residents), of apartment buildings were asked during the interviews. Fifty-five out of the 65 apartment building communities were randomly selected as ‘modelling subjects’ to establish both cost prediction models. The remaining 10 apartment building communities were treated as the ‘test subjects’ to examine the predictive capability and accuracy of both models. The distributions of dependent and independent variables of the 55 ‘modelling subjects’ are shown in Table 1.

Table 1: The distributions of dependent and independent variables of 55 modelling subjects

	Independent variables						Dependent variable
	Building age (year)	**Apt. unit number** (unit)	**Floor number** (floor)	**Average sale price** (NTD/ping)	**Total floor area** (ping)	**Public floor area** (ping)	**Actual O&M cost** (NTD/mon)
Minimum	1	20	6	82000	1357	184	100000
Maximum	18	800	33	555000	34431	7155	1672473
Average	5	187	17	210763	8023	2112	450967

Table 2: The correlation coefficients among the six design variables of apartment buildings

	Building age (X_1)	**Apt. unit number** (X_2)	**Floor number** (X_3)	**Average sale price** (X_4)	**Total floor area** (X_5)	**Public floor area** (X_6)
Building age (X_1)	1					
Apt. unit number (X_2)	–0.04	1				
Floor number (X_3)	–0.45	0.49	1			
Average sale price (X_4)	–0.11	–0.38	0.04	1		
Total floor area (X_5)	–0.02	**0.84**	0.55	–0.14	1	
Public floor area (X_6)	–0.14	**0.77**	0.58	–0.08	**0.93**	1

The regression model

A stepwise regression procedure on the sampling data was used to identify significant independent variables for predicting the O&M costs of apartment buildings. The preliminary regression model of O&M cost of apartment buildings is given in Equation 1:

$$Y = \beta_0 + \beta_1 \times X_1 + \beta_2 \times X_2 + \beta_3 \times X_3 + \beta_4 \times X_4 + \beta_5 \times X_5 + \beta_6 \times X_6 + \varepsilon \quad (1)$$

where Y is the predicted O&M cost (NTD/month); X_1 is the age of the apartment building (year); X_2 is the number of apartment units in the building (unit); X_3 is total number of floors (floor); X_4 is the average sale price (NTD/ping); X_5 is the total floor area (ping); X_6 is the floor area of public used area (ping); and the coefficients β_i (i = 1, 2, …, 6) represent the corresponding constants.

The SPSS statistical software system was used for establishing the regression model. To avoid the problem of ‘multicollinearity’ in multiple regression analysis, the correlations among the six design variables were first examined. As shown in Table 2, X_2 (number of apartment units), X_5 (total floor area) and X_6 (public floor area) are highly correlated (coefficients r = 0.84, 0.77, 0.93). Since the information of ‘total floor area’ is usually available at preliminary design stage of an apartment building, and it is a more objective measure of the ‘scale’ of apartment building projects, X_5 was kept and X_2 and X_6 were eliminated from the regression model. A forward stepwise regression procedure was employed and multiple regression analysis was performed on the remaining four independent variables.

The results of the regression analysis indicated that approximately 76% (adjusted-R^2) of the variation in the dependent variable Y (O&M cost) can be explained by two significant independent variables X_4 (average market unit price, $\beta_4 = 0.9$, $p < 0.01$) and X_5 (total floor area, $\beta_5 = 52.7$, $p < 0.001$); and the independent variables of X_1 (building age) and X_2 (household number) appeared to be insignificant (Table 3). The final regression model was reformulated by eliminating the insignificant independent variables as Equation 2:

$$Y = -143614.0 + 0.9 \times X_4 + 52.7 \times X_5 \quad (2)$$

With the established regression model, one can predict the O&M cost of an apartment building at preliminary design stage. By providing the data of two design attributes, average sale price (X_4) and total floor area (X_5), of an apartment building into Equation 2, its O&M cost can be calculated and predicted.

Table 3: Results of multiple regression analysis of the O&M cost prediction model.

	Regression model Y: O&M cost (NTD / month) (N = 55)		
	β	**SE**	**T-value**
Building age (X_1)	–2970.6	7976.6	–0.37

R-square (R^2)		0.76	

Notes: *p < 0.05; **p < 0.01; ***p < 0.001.

The artificial neural network (ANN) model

Data of the six design attributes (inputs) and the O&M costs (output) of 55 modelling subjects were used as the training sample, and back propagation learning algorithm was used along with the software Neuralyst v 1.4 to establish the ANN O&M cost prediction model. It's decided that multilayer perceptrons (MLP) network architecture was used, and that the six design attributes defined as the six input neurons and the O&M cost as the output neuron of the network architecture. The following steps were taken to establish the ANN model:

1. *Data normalization*: data of six input variables of 55 subjects were first normalized by employing the 'along channel normalization' method, and then loaded into the software along with the O&M cost data (output variable).
2. *Parameter setting*: a set of parameter values, such as the number of hidden layers and the number of neurons in hidden layers, learning rate and momentum, were assigned in the software.
3. *Network training*: for the set of parameter values assigned, the back propagation algorithm was used for neural network training, in which weights of a network are iteratively modified to minimize the overall mean or total squared error between the desired and actual output values for all output nodes over all input patterns. As a result, a 'root mean squared error (RMSE)', indicating the forecasting error of the set of parameter values was generated.
4. *Trial and error*: by repeatedly assigning different sets of values of hidden layer number (0, 1, 2), neuron number in hidden layers (4, 5), learning rate and

momentum (both between 0 and 1), as well as performing neural network training, a best combination of learning rates, momentum, number of hidden layers, number of neurons in hidden layers, learning rules and transfer functions that resulted in a minimal RMSE was identified.

As a result, the ANN model with an architecture consisting of an input layer of six input neurons, a hidden layer of five neurons, and an output layer of one neuron was established (Figure 1). The most popular learning rules, generalized delta rules and a sigmoid transfer function were used for the output neuron, the learning rate was 1.0, the momentum was 0.85, the number of iteration was 2981, and the root mean squared error (RMSE) was 0.031.

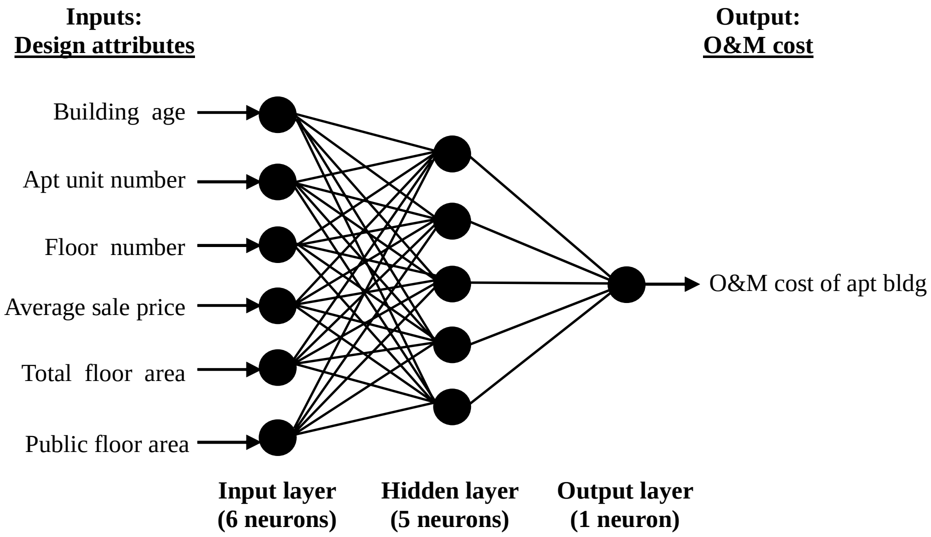

Figure 1: The neural network architecture for predicting O&M costs of apartment buildings

With the established ANN model, one can predict the O&M cost of an apartment building at preliminary design stage. By providing the data of six design attributes of the apartment building as the inputs to the ANN model, its O&M cost can be generated by the ANN model as the output.

RESULTS AND DISCUSSION

Predictive capability and accuracy of prediction models

The predictive capability and accuracy of both models were examined by comparing the actual O&M costs of 10 apartment building test subjects with the O&M costs predicted by the proposed regression model and ANN model. Data of the six design attributes and the actual O&M costs of the 10 test subjects are shown in Table 4.

To obtain the predicted O&M costs of the 10 test subjects from the 'regression model', the data of average market sale price (X_4) and total floor area (X_5) were fed into Equation 2 and their O&M costs calculated. To obtain the predicted O&M costs of the 10 test subjects from the 'ANN model', the data of six design attributes were provided as the inputs to the ANN model, and their O&M costs generated as the outputs. The O&M costs predicted by both models as well as their deviations from the actual O&M costs (percentage of error) are shown in Table 5 and Figure 2.

Table 5: The actual O&M costs and those predicted by the regression and ANN models

Test subjects	**Actual O&M cost** (NTD/month)	**Regression model**		**ANN model**	
		Predicted O&M cost (NTD/month)	**% error**	**Predicted O&M cost** (NTD/month)	**% error**
TS-1	68445	89519	30.8 %	65756	–3.9 %

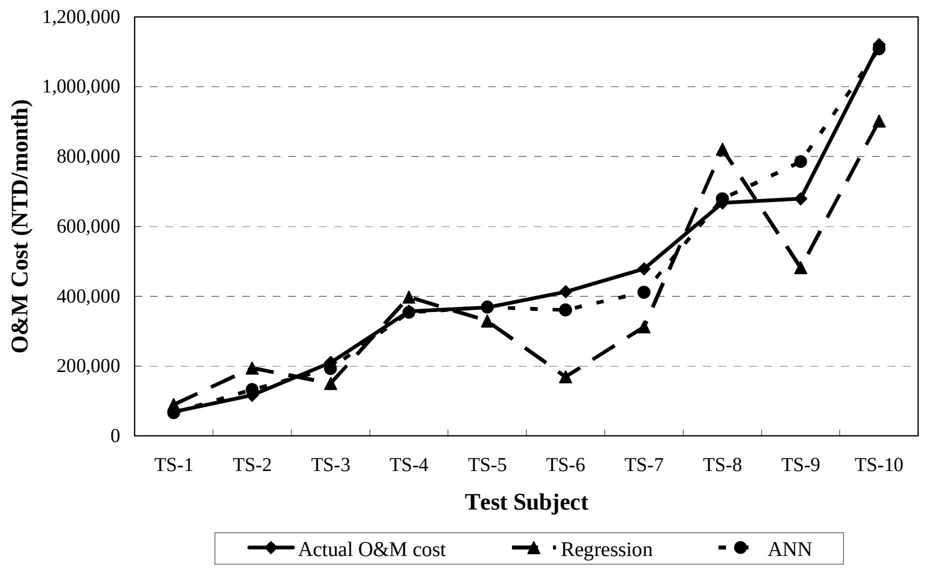

Figure 2: Comparison of actual O&M costs and those predicted by regression & ANN models

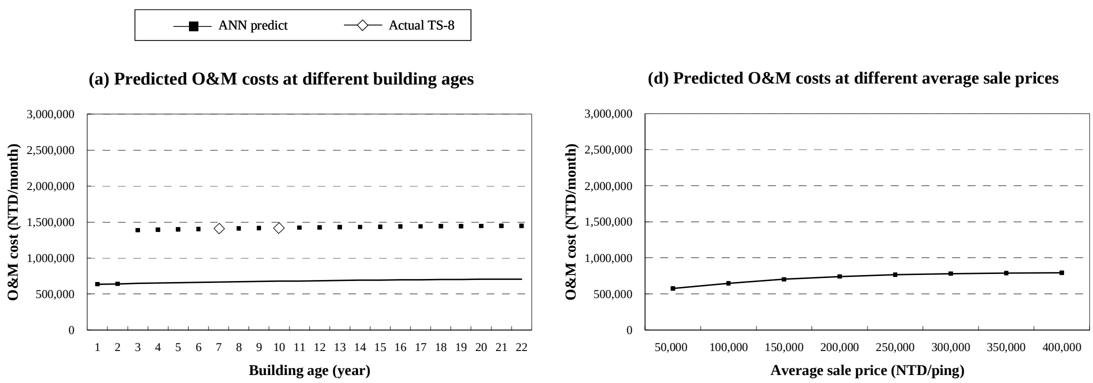
In Table 5, it can be observed that the ANN model generally outperformed the regression model in predicting O&M costs of apartment buildings. The O&M costs predicted by the ANN model have lower average absolute errors than those predicted by the regression model (7.3% vs. 31.4%). The absolute errors of the costs results predicted by the ANN model ranged from 0.2 to 15.7%, with an average absolute error of 7.3%, whereas the absolute errors of the O&M costs predicted by the regression model ranged from 10.6 to 66.9%, with an average absolute error of 31.4%. This means the deviations of the predicted costs by the ANN model from the actual costs are smaller, and indicates that the ANN model generates more accurate cost results.

Besides, the ANN model also generated cost results with smaller maximum absolute error than the regression model (15.7% vs. 66.9%). This means the degree of possible errors of the ANN model is smaller than that of the regression model, and indicates that the ANN model generates more stable cost results.

In conclusion, the ANN model is a more accurate and stable cost prediction model (with a maximum error around 15%) as compared with the regression model. The O&M cost results predicted by the ANN model appear to be satisfactory.

The ANN model: predicting trends of building O&M costs

To demonstrate how each of the six design attributes affects building O&M cost in the ANN model, as well as to test the ANN model's estimation ability to generalize and predict the trends of O&M costs correctly for a given design attribute, TS-8 was randomly selected from the 10 test subjects, whose data of design attributes and O&M cost were used for further analyses. To examine the effects of a design attribute, say 'building age', on building O&M costs, the remaining five design attributes of TS-8 were held constant in the ANN model, and different 'building ages' were input into the ANN model to obtain corresponding predicted O&M costs. The trend of predicted O&M costs at different building ages and the actual O&M cost of TS-8 (666 939 NTD) at its building age (10 years old) were plotted and compared. The trend results of the predicted O&M costs related to the six design attributes were analysed similarly and illustrated in Figure 3 (a–f).



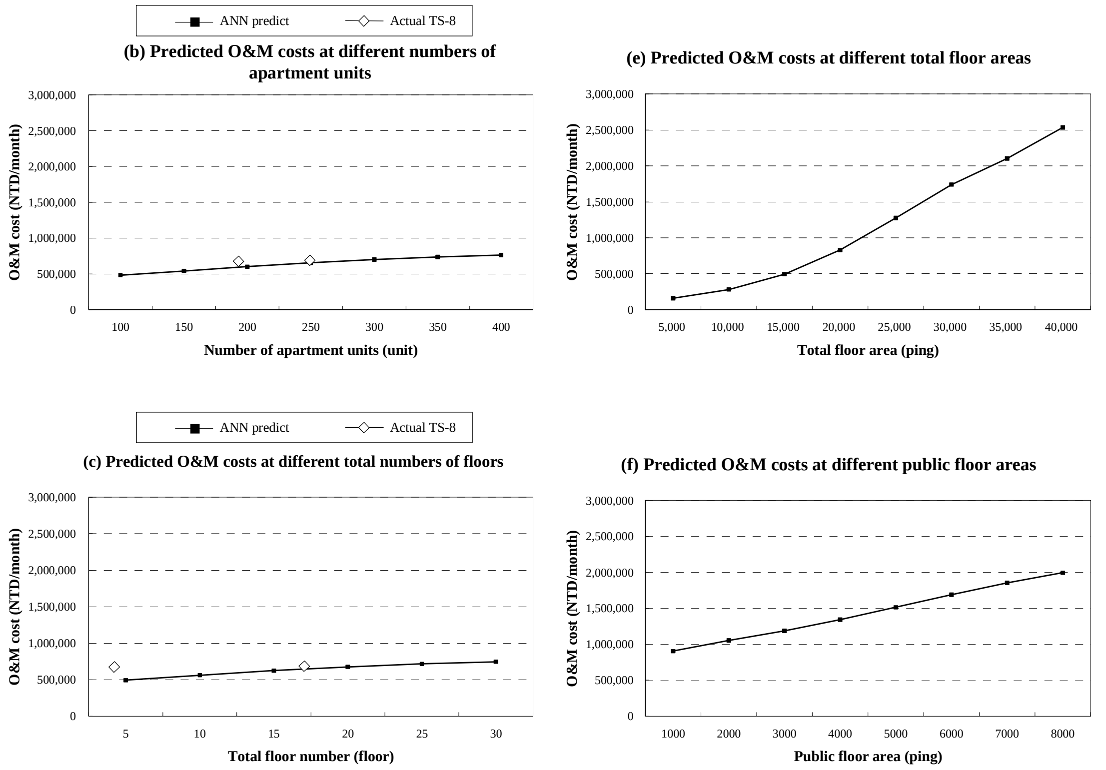


Figure 3: The trend results of the predicted O&M costs related to each of the six design attributes in the ANN model vs. the actual O&M cost of TS-8

The effect of each design attribute on building O&M cost in the ANN model is revealed by the slope of its trend line. As indicated in Figure 3, for a particular apartment building with design attributes similar to TS-8, it's predicted by the ANN model that its O&M cost is primarily affected by its 'total floor area' and 'public floor area' (steeper slopes), less affected by its 'apartment unit number', 'total floor number' and 'average sale price', and does not change much at different stages of its building life. The trend results of O&M costs of apartment buildings with different characteristics and design attributes can be analysed and examined similarly.

The estimation ability of the ANN model to generalize and predict the trend of O&M cost correctly is indicated by the relationship between the actual O&M cost of TS-8 and the predicted trend line in each of the six plots in Figure 3. Generally speaking, the actual O&M cost of TS-8 is relatively close to the predicted trend line in each plot, suggesting that the ANN model developed is effective in generalizing and predicting the trends of the O&M costs of apartment buildings.

CONCLUSIONS

This research was motivated by the urgent need of an analytic method to predict the life cycle O&M cost of an apartment building at its preliminary design stage. Typical operation and maintenance tasks carried out in existing apartment buildings in Taiwan and associated costs were examined. Six design attributes (building age, number of apartment units, number of floors, average sale price, total floor area, public floor area) of apartment building projects which could affect their life cycle O&M costs were then identified. The regression model and the artificial neural network (ANN) model were developed to predict O&M costs of apartment buildings at their preliminary design stages. The six design attributes were designated as the inputs or independent variables of both models, and the O&M cost as the output or dependent variable of both cost prediction models. Data related to the six design attributes (inputs) and the O&M costs (output) of apartment building test subjects were used to examine and compare the predictive capability and accuracy of both models.

The ANN model appears to be a more accurate and stable O&M cost prediction model as compared with the regression model. In particular, the ANN model generates O&M cost prediction results with a lower average absolute error and a lower maximum absolute error than the regression model. The O&M cost results predicted by the ANN model appear to be satisfactory (with a maximum error around 15%).

Although producing acceptable results, this research is only in its preliminary stage in pursuit of methods to predict the O&M costs of apartment buildings at the preliminary design stage. To ensure that the ANN model provides the developers and architects of apartment building projects with reliable prediction results, the ANN model requires further testing and validation. A number of research tasks to be fulfilled are identified.

In the regression model, it seems to be a problem when trying to establish the relationship between the ages, sale prices, O&M costs of existing buildings, and to predict future O&M costs (at different ages) of today's building based on its current 'sale price' and the relationship found from yesterday's buildings, because it assumes a relationship between input and output variables. As for the ANN model, it is not a problem, since it only tries to learn from historical data and experience, and does not intend to derive a theory about the underlying law governing the system. Nonetheless, the applicability of the six design attributes of the ANN model will be further examined and validated.

Other potential design attributes that may affect building O&M costs will also be included and tested. More apartment buildings test subjects, especially those with great variances in various design attributes (inputs), will be used to test the accuracy and stability of the ANN model in cost predictions of 'cross-sectional' subjects. Besides, the ANN model will be tested against subjects with year-by-year O&M cost data to examine its accuracy and stability in cost predictions of 'longitudinal' subjects.

ACKNOWLEDGEMENT

The authors would like to thank the National Science Council of the Executive Yuan of Taiwan for sponsoring this research work (Project No. NSC 91-2211-E-011-051).

NOTES

1. NTD = New Taiwan Dollar, 1 GBP ≈ 64 NTD; 'Ping' is a conventional measure of area often used in Taiwan, 1 ping ≈ 1.8m × 1.8m.

STRUCTURAL EQUATION MODEL OF SAFETY CULTURE AND WORKER BEHAVIOUR IN CONSTRUCTION

Andi Andi[1]

Department of Civil Engineering, Petra Christian University, Jalan Siwalankerto 121–131, Surabaya 60236, Indonesia

The organizational preconditions to accidents are perceived as increasingly important for construction safety management. Empirical examination of the influence of organizational safety culture, including management commitment, safety rules and procedures, communication, competence, work environment and worker's involvement, on workers' safety behaviour is an important step to understand this notion. Data were collected from three large construction projects using a questionnaire and a total of 207 valid questionnaires were returned and formed the basis for structural equation modelling and subsequent analyses. The analyses results indicate only four safety culture factors having significant influence on workers' behaviour. The research concludes that top management commitment is a pivotal driver of safety culture, and the workers' behaviour can be controlled using the combination of prescriptive and discretionary approaches.

Keywords: accident, questionnaire survey, safety culture, structural equation model, worker behaviour.

INTRODUCTION

Mohamed (2002) mentions that the construction industry has a poor safety record compared to other industries. There are many perceptions indicating that accidents in construction projects, which can range from minor injuries to loss of life, originate from workers' unsafe acts (Hinze 1997). In other words, unsafe acts (or sometimes called human errors) are the main causes of accidents. However, this perception is disputed by Reason (1990), who states that attempts to reduce accidents by focusing only on unsafe acts will not be able to tackle the underlying causes. Reason (2000) give the example of mosquitoes as unsafe acts. They can be swatted one by one, but they still keep coming. The best remedies are to create more effective defences and drain the swamps in which they breed. The swamps, in this case, are the ever-present latent factors lying beneath the organizational and managerial factors.

Recently, there has been a shift in managing safety from a measurement that considers just accident rates to a management that takes into account safety culture (Cooper 2000). This consideration is driven by awareness that the underlying causes of accidents originate from organizational and managerial factors (Reason 1995). Therefore, attempts to measure safety culture constitute a

[1] andi@peter.petra.ac.id

very important step in order to generate safe working conditions and in the end to reduce accident rates.

Empirical studies considering safety culture have been progressing in the manufacturing industry (Cheyne *et al*. 1998; Oliver *et al*. 2002), but are still very limited in construction. In his study, Mohamed (2002) found a significant influence of safety culture on construction worker behaviour. The study however was limited to the direct relationship between safety culture and worker behaviour, and did not examine the interaction between safety culture factors. Considering the limitation, this paper attempts to propose and examine a causal model representing direct and indirect relationships between safety culture factors and worker behaviour.

SAFETY CULTURE

Safety culture is a sub-component of corporate culture, which alludes to individual, job and organizational features that affect and influence health and safety (Cooper 2000). Uttal (1983) defines it as shared values and beliefs that interact with an organization's structure and control systems to produce behavioural norms (cited in Cooper 2000). Another definition by Turner (1992) is the set of people's shared beliefs, norms, attitudes and expectations shared collectively by members of a society, organization or group.

Defining and measuring safety culture are complex tasks when all of the above facets are considered. In this study safety culture is composed of six main factors, i.e. top management commitment, safety rules and procedures, communications, workers' competency, workers' involvement and work environment. The following sections briefly discuss these safety culture factors.

Top management commitment

According to Reason (1997) a safety programme should be initiated from the top management of an organization. The top management should formulate a policy indicating a commitment to safety. This step will lead other policy makers concerning safety. Without it, it is very difficult to achieve a successful safety programme (Cheyne *et al*. 1998; Mohamed 2002). Marsh *et al*. (1998) have shown that management commitment was the most significant measure to determine and influence safety performance in 26 building sites across the United Kingdom.

Safety rules and procedures

The presence of safety rules and procedures may minimize accidents caused by unsafe conditions because they give a clear picture of safety programme implementation in construction projects (Pipitsupaphol 2003). The problems often found are that the rules and procedures are difficult to understand and implement, inappropriate with the current conditions, and there is over-specification.

Communications

Communications-related problems have been repeatedly reported in the literature to be responsible for many human errors resulting in structural failures, design quality problems, building defects and design defects (Andi and Minato 2004). It is thus important, in order to support a site safety programme, to make available appropriate information lines from management to workers and vice versa. Information such as unsafe conditions and new rules and procedures are very important to support the safety programme.

Worker competence
Workers' adequate knowledge, skill and ability in their work, especially towards risks and dangers in their work, may minimize accidents. These competences can be enhanced through training and appropriate workers selection (Mohamed 2002).

Work environment
Workplace factors are situations and conditions within the place where the workers work, which directly lead workers, as individuals or as a team, to initiate unsafe behaviour. This may cover such internal conditions as motivation, boredom, and also external conditions as time pressure and blaming culture.

Worker involvement
Workers' involvement is very important in building workers' awareness towards safety programmes. The form of involvement can be workers' participation during development of the safety programme and accident or unsafe act investigation and reporting. It is hypothesized that a higher level of involvement will give more positive influence to the safety behaviour.

A PRIORI MODEL

Figure 1 shows an *a priori* model representing the influence of safety culture on worker safety behaviour. The proposed model included six cultural factors and one worker behaviour factor. Each factor was composed of several indicators, and in total 39 indicators were used to measure the seven factors. The model also described the direct and indirect effects of safety culture factors, which were determined by consulting previous related research (Cheyne *et al*. 1998; Oliver *et al*. 2003; Mohamed 2002). There were 21 paths considered in the model, where each indicated a one-way effect (influence) from one factor to other factor.

RESEARCH METHOD

Data for the research were gathered by distributing questionnaires to construction workers. The questionnaire consisted of three parts, where the first part covered general information about the respondents and the project. The second part included the six factors of safety culture. Here the respondents were given a number of statements indicating the condition of each factor, and then asked to rate their agreement using a six-point rating scale from 1 (strongly disagree) to 6 (strongly agree). The final part captured the worker behaviour factor, which was composed of several indicators. The respondents were asked to rate the frequency of occurrence of each indicator using a six-point rating scale from 1 (never) to 6 (always).

The research employed the structural equation modelling (SEM) technique to analyse the data. The technique allows separate relationships for each of a set of dependent variables. It provides the appropriate and most efficient estimation techniques for a series of separate multiple regression equations estimated simultaneously (Hair *et al*. 1995). The first step in using the technique is to distinguish which independent variables predict each dependent variable by drawing upon theory, prior experience and the research objectives. Some dependent variables may become independent variables in subsequent relationships, giving rise to the interdependent nature of the structural model. Moreover, many of the same variables will affect each of the dependent variables, but with different effects. In the current research the structural model expresses the relationships between safety culture factors and worker behaviour, as shown in Figure 1.

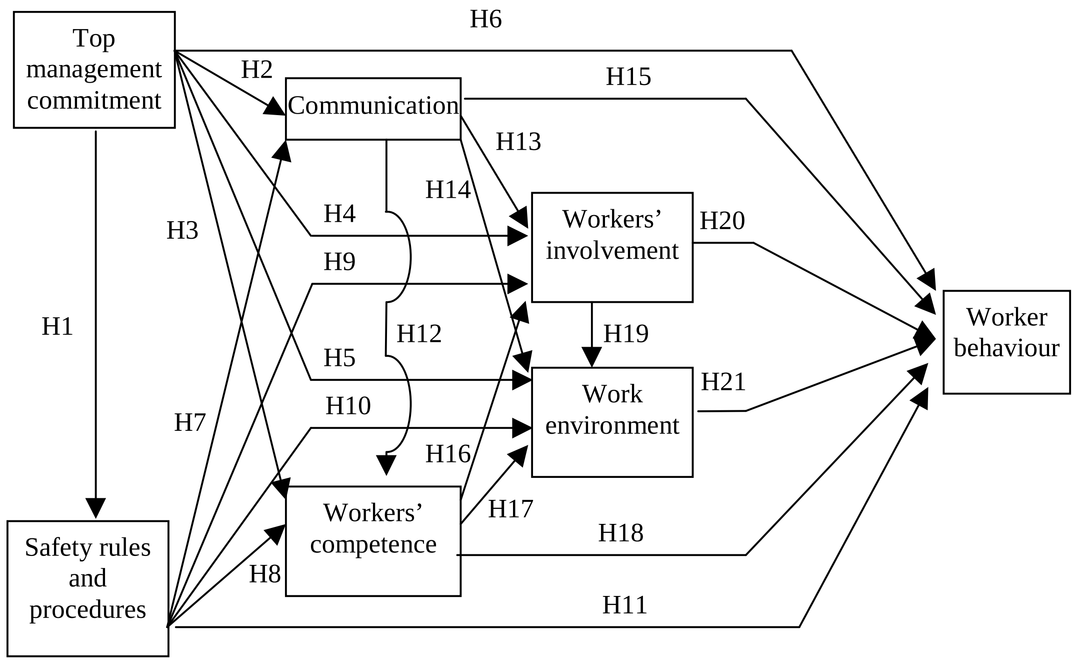

Figure 1: The *a priori* model

The analyses following the development of the *a priori* model (including factors and their respective indicators) were confirmatory factor analysis (i.e. to confirm that an indicator significantly indicates its respective latent factor), regression weight tests (i.e. to test whether the regression weight in each relationship is significantly not zero), model modification (if required), goodness-of-fit test (i.e. to evaluate the overall final model fit) and structural effects analyses (i.e. the strengths of direct, indirect and total effects between factors in the model).

RESULTS

Three ongoing construction projects at the time of the survey were approached. The projects included a shopping mall, office and clinic buildings. From these projects, a total of 207 valid questionnaires were successfully collected. The number of respondents gathered fulfilled the minimum requirement in using the SEM technique, i.e. five times the number of indicators.

CONFIRMATORY FACTOR ANALYSIS

In this step, each indicator was evaluated for its significance in contributing to its respective factor. The null hypothesis was that there was no significant contribution (α = 5%). The analyses performed showed three indicators of worker behaviour factors that were insignificant. They were then excluded from the model.

REGRESSION WEIGHT TEST

This step was to test each direct effect (21 paths) in the model. The null hypothesis was that there was no significant effect from one factor (e.g. top management commitment) to another factor (e.g. safety rules and procedures), with 95% confidence interval. Table 1 presents the analysis results. There are 11 paths that were insignificant (with p-value greater than 5%), and should be eliminated from the model.

Table 1: Regression weight test results

	F1	**F2**	**F3**	**F4**	**F5**	**F6**	**B**
Commitment (F1)	—	0.000*	0.006*	0.000*	0.260	0.330	0.747

Note: *Significant influence (at α = 5%).

MODEL MODIFICATION

From the previous analysis results, the *a priori* model was modified. The new model (Figure 2) incorporated only 10 paths.

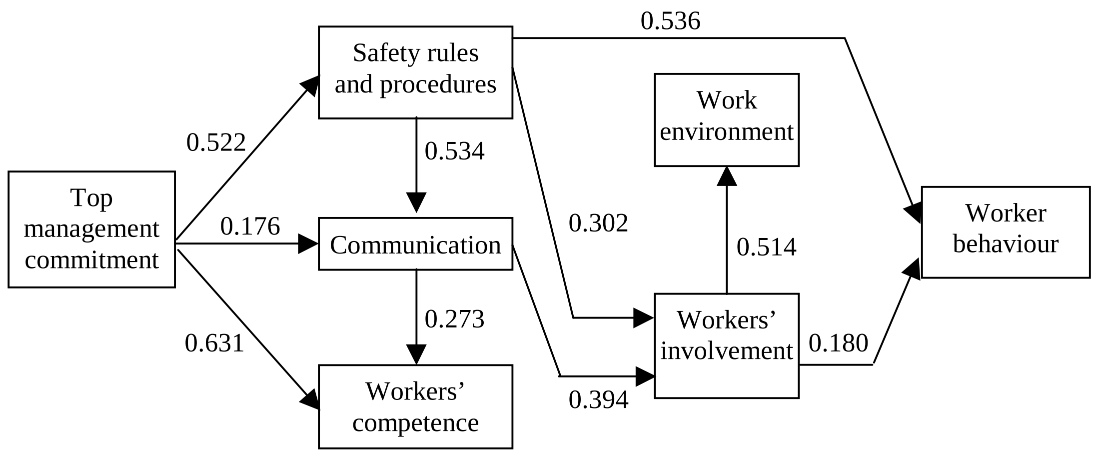

Figure 2: The new model

GOODNESS-OF-FIT TEST

The new model (Figure 2) was tested for its goodness-of-fit. Several indexes were used as shown in Table 2. It can be seen from the table that all indexes' value fulfils the condition for model fitting, thus the new model can be used as the basis for a description of the influence of safety culture upon worker behaviour.

STRUCTURAL EFFECTS ANALYSES

The strength of direct effects can be seen from Figure 2. Two safety culture factors directly influence worker behaviour, i.e. safety rules and procedures and workers involvement. Meanwhile, Table 2 presents the strengths of indirect effects in the model.

Table 2: Goodness-of-fit test results

Goodness-of-fit indexes	Test value	Condition		Remark
RMSEA	0.000	≤	0.08	Fit
GFI	0.987	≥	0.90	Fit
AGFI	0.968	≥	0.90	Fit
CMIN/DF	0.857	≤	2.00	Fit

Table 3: Indirect effects

	F1	F2	F3	F4	F5	F6	B
Commitment (F1)	—	0.000	0.295	0.129	0.352	0.181	0.359
Rules and procedures (F2)	—	—	0.000	0.146	0.210	0.263	0.092
Communication (F3)	—	—	—	0.000	0.000	0.202	0.071
Competence (F4)	—	—	—	—	0.000	0.000	0.000

Environment (F6)	—	—	—	—	—	—	0.000
Behaviour (B)	—	—	—	—	—	—	—

MEAN DIFFERENCES ACROSS PROJECTS

Once the model has been properly established, further comparisons between groups (projects) were considered. In particular, whether or not projects differed in their average perceptions of safety culture was examined. MANOVA and one-way ANOVA tests were performed on the measured safety culture factors. MANOVA was used to test for the effects of the project on each safety culture factor. A Box test was first employed, showing that there were statistically significant differences between the variance–covariance matrices across the different projects (Box’s M = 270.93, F = 6.071, p = 0.000). Further multivariate analyses display significant differences between the projects (Wilks’ Lambda = 0.301, F = 27.273, p < 0.001; Pillai’s criterion = 0.811, F = 22.744, p < 0.001).

Several one-way ANOVAs were then performed one for each dimension. Table 4 shows four factors that were statistically significant different, i.e. top management commitment, safety rules and procedures, communication and workers’ competence. From the mean values, it can be seen that the mall project possessed a better safety culture than the two other projects, especially upon the aforementioned four significant factors.

Table 4: ANOVA results

Safety culture factors	Mean values			*F*	*Sig.*
	Mall	Clinic	Office		
Top management commitment	4.34	3.61	3.30	5.51	0.00
Safety rules and procedures	4.03	3.77	3.51	6.38	0.00
Communication	3.53	3.27	3.14	10.04	0.00
Workers competence	4.51	3.85	3.51	9.03	0.00
Working environment	3.58	3.57	2.71	1.89	0.15
Workers involvement	3.60	3.58	3.48	2.71	0.07

DISCUSSIONS

The analyses results through the structural equation modelling indicate that safety culture influences construction workers' behaviour. Factors that influence worker behaviour (direct and/or indirectly) are top management commitment, safety rules and procedures, communication and worker involvement. One important thing found from the analysis is that top management commitment is the driver to develop a good or poor safety culture. The finding thus strengthens previous assertions on the importance of management commitment (Turner 1992; Pidgeon 1998).

Another noteworthy finding is related to approaches in controlling worker behaviour. Reason (1997) mentions that worker behaviour can be controlled in two ways, i.e. prescriptive and discretionary; and mixed controls, where the choice of control depends on several aspects. The analysis results confirm that worker behaviour can be controlled through the combination of both approaches.

Prescriptive control can be described as external controls, which are made up of rules, regulations and procedures that closely prescribe what actions may be performed and how they should be carried out. Such paper-based controls embody the system's collective wisdom on how the work should be done. This approach is shown in Figure 4 by the direct influence line from safety rules and procedures to worker behaviour. In this way, worker behaviour can be controlled by forming safety rules and procedures that are appropriate, easy to understand and implemented by the workers. Workers then should follow the rules and procedures, and sanctions will be given for any violations.

On the other hand, discretionary controls are derived from the knowledge and principles through training and experience, which form the internal controls. This research shows that internal controls can be performed by enhancing workers' awareness towards the importance of safety. This can be done by involving and conducting a two-way communication with the workers about safety at work, and also giving safety training to increase the workers' knowledge and experience.

The mean scores in the three projects indicated that in general the workers' perception towards safety culture is quite good (mean score more than 3.00). However, there are significant differences between the three projects, where the mall project demonstrates the best safety culture. It is interesting to note that the clinic and office projects were performed by the same contractor organization. It can be said therefore that the contractor constructing the mall project possesses a better safety culture than the contractor on the two other projects.

CONCLUSIONS

The research has examined the influence of safety culture (and its factors) on workers' behaviour through structural equation modelling. The resulting model indicates that safety culture plays an important role in influencing workers' behaviour, through such factors as management commitment, safety rules and procedures, communications and workers' involvement. The model highlights management commitment as the first most important step in initiating appropriate safety culture. In addition, workers' behaviour can be controlled through the combination of prescriptive and discretionary approaches.

MEASURES OF INFORMATION FLOW FOR LEAN DESIGN IN CIVIL ENGINEERING

Effi Tribelsky[1] and Rafael Sacks[2]

Civil and Environmental. Engineering, Technion – Israel Institute of Technology, Haifa 32000, Isreal

Research to date concerning application of lean thinking to civil engineering design suggests that applying the principles in a systematic fashion may improve the process, reduce errors and reduce negative iteration. However, there is a lack of any method for measuring information flow during the design process. This study proposes mapping and measuring the flow of information in the process of detailed design. Measures and indices of flow were formulated based on examination of empirical data compiled by monitoring flows of data and information in the detailed design stage of each of fourteen construction projects. The data was drawn from the computerized databases created through use by practitioners of an Internet-based construction project management tool. The indices and information flow graphs being developed are intended to assist in identifying faults or bottlenecks in the process as they happen, providing clear indications of disruptions in the information flow. As such, they are important tools for research of engineering design and for practical use in design management.

Keywords: measurement, information technology, design management, lean thinking, project management.

INTRODUCTION

Like most processes, the detailed design process for a civil engineering facility can be wasteful or efficient. Process efficiency is defined by the nature of the reciprocal activities between process participants, with a large measure of output effectiveness resulting from the desire to avoid unnecessary repetition of tasks. Process efficiency and outcome effectiveness are key issues in measuring the likelihood of success of a project. Achieving this requires measuring c[2]apabilities and relative scales to enable follow up and comparison between various activities, beginning at the single process level and up to a full and detailed process.

But how can we tell at any particular point in time that a design process wastes inputs and is not expected to yield optimum output? How can we tell if the flow of design information is efficient? Can we assemble and present a value flow path map dynamically, while the process is taking place?

The difficulty in providing a response to these questions is due to the lack of indices or tools to assist in analyzing and quantifying the progress in generating value along the information flow path. The research detailed in this paper aims to respond to this

[1] efit@technion.ac.il

difficulty by presenting a model for measuring information flow efficiency, and attempting to show the correlation between this and the final results of the project.

"Lean" production, which has its roots in the Japanese automobile manufacturing plants, found its way into many other manufacturing industries, worldwide. The method is centred on waste reduction and facilitating flow in various manufacturing processes (Ohno 1988; Womack *et al.* 1991). It has also impacted on the construction sector, and numerous researchers and practitioners have explored the possible practical implications on the industry (Alarcon *et al.* 2005; Ballard and Howell 2003; Josephson and Hammarlund 1999; Sacks *et al.* 2003).

Many studies have shown that there is no lack of waste, in its various forms, in civil engineering projects (Fayek *et al.* 2003; Koskela 2004); it can be found at all project stages and all managerial levels. Planning and managing the design process presents complicated managerial problems for project managers. Choosing the right team, outlining a work plan and controlling the performance of consultants are the major criteria determining the success or failure of a project.

Waste in engineering design has many facets, beginning with partial utilization of the engineering solution space and loss of opportunities, through wasteful management and up to creation of negative and ineffective design outputs. The scope of work repeated at building sites is conservatively estimated at 6% of the project value (Love *et al.* 2000); more than half of this rate results from various design failures. Implementing lean principles might help eliminate this effect, but there is no method for measuring the flows of information in the design process and the effectiveness of those flows. In the words of Sir William Thomson (Lord Kelvin) "If you cannot measure it, you cannot improve it."

Since many researchers worldwide have recognized that design contributes decisively to the success of the final product, a wide range of research has dealt with managing the process. Although most of the research has centred around manufacturing industries, such as the automobile industry, the aircraft industry and so on, a few researchers have studied design management in the construction sector. Most studies in this field deal with operational management of the design, and concentrate on management of design offices, their day to day operations and making processes efficient (Bashir and Thomson 1999; Chan and Yu 2005; Thomas *et al.* 1999). Only a few studies have dealt with value management and design flow with a content approach. How to improve information flow and design management in terms of cycle-times, batch sizes, intra-process reciprocal relationships and the quality of the information created have been studied to a lesser and more limited extent (Chang and Ibbs 1998; Thomson *et al.* 2006).

According to Formoso and Tzortzorpoulos (1998), the currently accepted design process doesn't necessarily reduce the ramifications of partial information and uncertainty, doesn't guarantee that the required information for completing the full design is sufficient, and doesn't reduce the level of non-correspondence between the various design documents. Ballard and Koskela (1998) point out that design managers try to deal with some of the above-mentioned problems using project management, concurrent engineering, process processing, value management, organization of multidisciplinary teams, and modern methods of electronic data transfer and data sharing. According to Ballard and Koskela (1998), with traditional design, preference is given to managing a sequence of tasks (using the critical path method) as opposed to flow and value management. The starting point of the process is the assumption that there is a single good planning response to each task. If the solution is complex, iterations are performed on the chosen solution until an agreed-upon solution is achieved. This approach reduces the solution horizon, leads to the loss of valuable time for the rest of the process, and damages the design process efficiency.

A major foundation of the lean management method is based on identifying the product flow route along the production path and mapping the product value amassing process along this path (Womack and Jones 1998). The design process is similar in nature to the production process (Ballard 2000), but while in the typical production process machines and workers produce tangible products, in the design process consultants and designers work together to translate ideas and needs into tenders and documents. Other differences are driven by the target function of the production system. While classical manufacturing production systems encourage minimization of variance among its products, and sees rework as waste, the design mechanism draws its power from continuous positive iteration and continuous improvement during the process. Nevertheless, the same features of flow, such as bottlenecks, batch size and control are observed in both design processes and production processes.

The accepted means of communication between project managers and consultant teams don't encourage flow continuity and don't support the utilization of the full possible solution space. Identifying and mapping information flow channels in design projects and exposing designers' behaviour patterns would allow identification and neutralizing of focal points of waste and identification of the major locations where increase in value takes place, as well as consolidating communication methods in order to fully utilize the design process and improve its flow.

The following sections explain the aims and method of the research, describe a procedure for mapping information flows, propose a set of indices, and present initial conclusions of the research to date.

AIMS AND METHODS

This study aims to provide a set of measures and indexes designed to assist in quantifying information flow during the design process of a constructed facility. Use of these measures and indexes is intended to help project managers and participants identify bottlenecks, large batch sizes and long cycle times in the process as it progresses. Providing the clarity of visualization of the value flow path of the product design may enable short-term corrective action or long-term re-engineering of design processes.

The research method comprised 5 stages:

1) Examination of typical information flow patterns during detailed design. To this end, 14 various projects were selected and their information flows were recorded and studied.
2) Identification of the raw data that could be used as a basis for computation of measurement indices. From this, the units of measurement were defined.
3) Definition and preparation of information flow maps in order to visualize information flows.
4) Formulation of information flow indices and methods for their computation.
5) Validation of the indices by measurement using the project data measured, and comparison of the flow patterns revealed in light of actual project outcomes.

The following sections describe each of the first four steps; the fifth stage is currently in progress.

PROJECT DATA COLLECTION

Detailed data was collected from fourteen projects in order to provide a basis for proposing an array of indices. The indices measure rates and patterns of generation of design information, dissemination, batching, and other features. The projects examined were all part of an airport relocation. The whole project, whose total cost is estimated at $250M, included runways, hangars, service facilities, technical areas, flight infrastructures, water and sewage infrastructures, operational infrastructures, electrical systems, communication power stations, facilities, fuel lines, administrative areas and living quarters. Since all the projects were managed by the same developer, they had similar profiles, making it easier to compare the different projects. However, each project had a different team, including the designers and managers, thus allowing each project to be taken as a separate case.

Data was collected on three complementary levels (see Figure 1), so that the indices proposed could be verified by computing and comparing their values for the separate data sets collected for each project. The first level was retrieval of data describing information flow from the information transfer data log compiled automatically by the @View project management intranet application used to manage the projects (www.atview.com, Ramdor 2006). The software enables the use of the internet for centralized management of all project information, including CAD files, meeting summaries, presentations, time tables, task assignments and additional information. The record of uploads and downloads of files and any views of them that is saved in the journal log includes the time at which the activity was performed, the names of those who carried it out, and the file names where relevant. The data covers a wide range of the information transactions performed in the project. The activity types were divided into six categories: uploading, updating the version of, viewing, erasing, moving and copying files. Using the journal logs enabled collection of a large sample of documented, detailed and reliable information over extended periods.

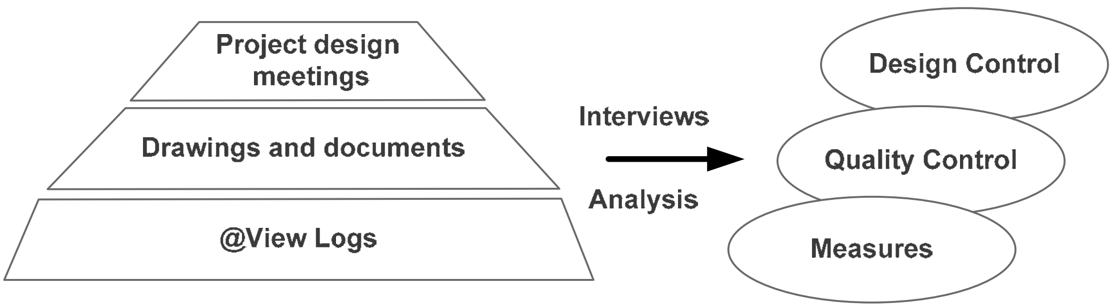

Figure 1: The three information sources, processing methods and validation systems

Understanding the value accumulation mechanism of design outcomes along the information flow path requires in depth analysis of the project drawings; this is the second level of data collection. The information management systems built into the @View software maintain all the versions of every drawing that was uploaded to the system throughout the life of the project. By comparing a drawing version to its predecessor, and by tracking the changes in the drawings by using view and compare software such as Autovue (www.cimmetry.com, Cimmetry Systems 2006), the nature and quality of all of the changes made can be examined. Mapping the changes in drawings, identifying the motivation for making them, and estimating their influence on information flow, helped to sort information movements and allowed the development of flow indices based on the information content that could not be based on the movements recorded in the journal logs. The third level was a series of structured observations of 86 design progress meetings that took place in the projects. The observations allowed collection of complementary information concerning design contents and contexts, the manner in which the meetings took place, difficulties during the formulation of the solution, the dynamics of the participants and their activities, and the general progress of the each project. Data collection, examination and analysis assisted in creating indices of the flow, and in defining the impact of the background conditions which influenced the quality of the information flow and the success of the projects. A structured and detailed method for measuring the influence of background conditions on the information flow was proposed in this study but is beyond the scope of this paper.

INFORMATION MEASURES

Figure 2 shows the different views of the same information object and demonstrate the difference between one information object to another.

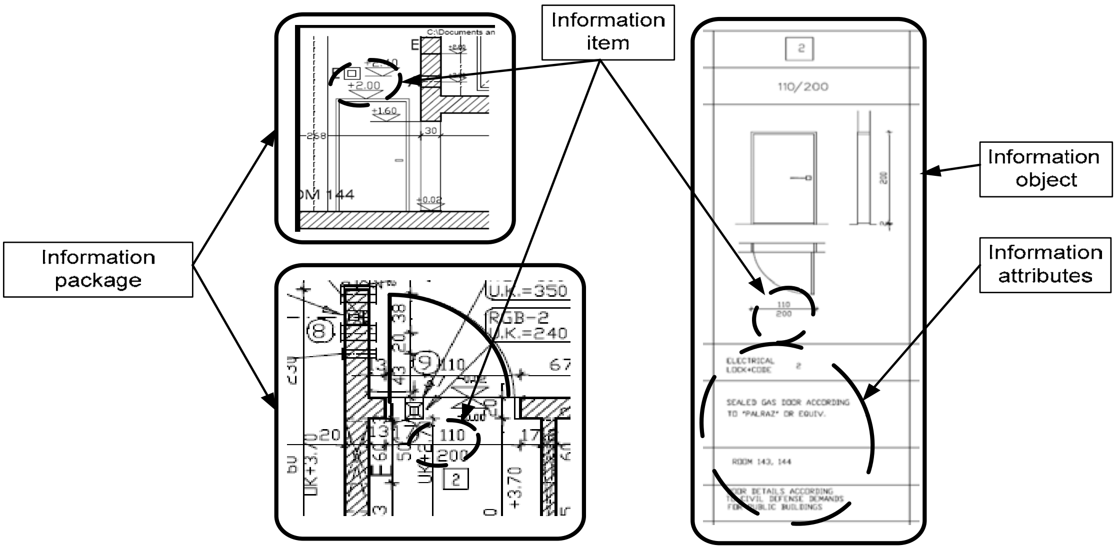

Figure 2: Graphical representation of types of information data

1. An *information package* is a view in a drawing, a text document, worksheet or data table, a page of calculations, etc., whether on a printed page or in a computer file. Where 2D CAD drawings are the medium of communication – which is still the most common method in civil engineering design – information packages are the basic units that are transferred between design project team members. If BIM is used, the information package could represent an entire model.
2. An *information item* is a single piece of information. It may be textual (a number in a bill of quantity, a label or dimension on a drawing, a clauses in a specification) or graphic (a line, arc or hatching in a drawing). An information package therefore represents a set of information items.
3. An *information object* is a distinct component of a building or facility with technical and engineering attributes and characteristics. In the literature, objects

are defined as having form, function and behaviour. Most objects are tangible, such as ceilings, windows, chillers, pipes, cables, walls, beams, etc., but some are intangible, such as space, passageway, etc. In projects where 2D drawings are the medium of communication, information objects are defined through their depictions in drawings, lists and other documents – i.e. in information packages. Each information object will commonly appear in multiple information packages.

4. An *information attribute* is a technical, engineering or management attribute of an information object such as its dimensions, material type, supplier name, colour, price, etc. The value of an information attribute may be displayed in any number of information packages.
5. An *action* is performed by a team member to communicate information. This most commonly involves transfer in one form or another of an information package, such as uploading a file to a central project server, delivering a paper document or similar activity. In some instances individual information items are communicated, such as when a single attribute is conveyed in discussion. A *publication* action is the transfer of any information from the private to the public domain, accomplished by posting it in a location accessible to relevant project participants.
6. A *project event* is an event in a project's lifecycle at which there is a peak in demand for information. Examples are preplanning meetings, design coordination meetings and presentations.

MAPPING INFORMATION FLOWS

The information flow graphs (IFGs) shown in Figure 3 and Figure 4 are based on the information transactions registered in the journal logs of the project intranet software and on the outcomes of the process analyses. The maps describe the information exchange between project participants while emphasizing information transfer, its trend and purpose.

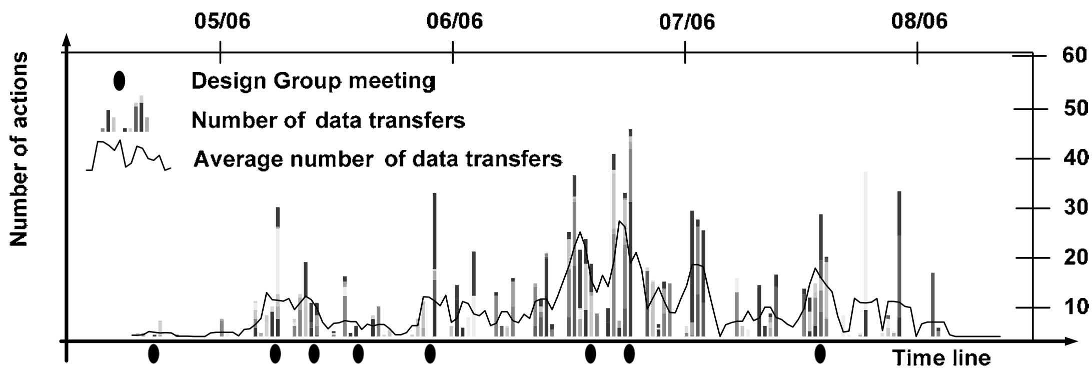

Figure 3: Graphical representation of IFG (Information Flow Graph) – data transfer density
The graph is displayed to managers with colour-coding according to design discipline.

The graph shown in Figure 3 demonstrates the handling time for transmitted information, assists in estimating information batches, reveals bottlenecks, and assists in identifying inadequate behaviour of consultants; it is a tool in the hands of the project manager for identifying obstructions and failures during the design process.

The IFGs' enable visualization of the nature of the process, how it progresses and how and when the information exchanges are performed. Identifying large batches, finding

unnecessary handling delays and late responses are just some of the insights that can be achieved by viewing the map. Planning the process using the flow map, and performance vs. planning control, will enable measure most of unique activity characteristics for the design process and will be used as a qualitative tool during the entire
process.

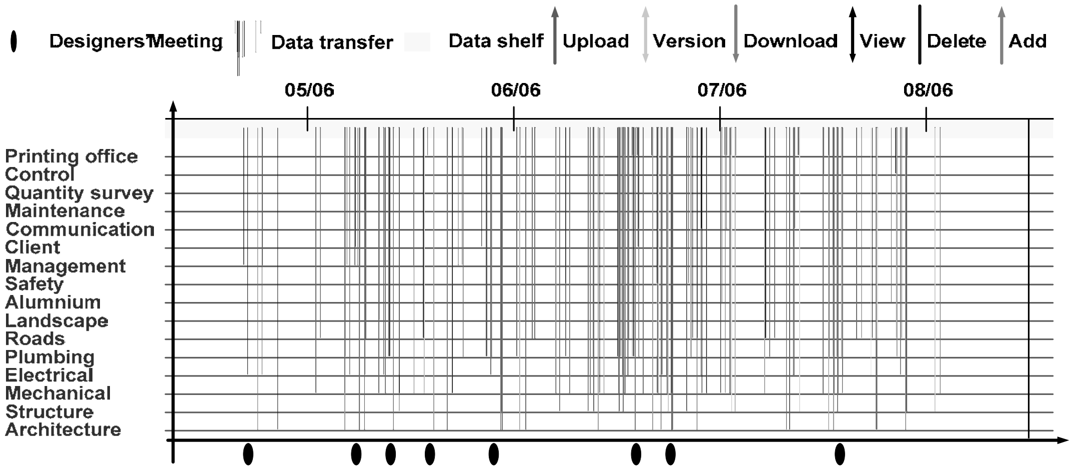

Figure 4: Graphical representation of IFG – number of data transfer actions

INFORMATION FLOW INDICES

Eight central indices were developed to assist in quantifying and characterizing information flow in the project. They are summarized Table 1**.** The following sections are dedicated to a general description of those indices. The indices make use of the technical terminology detailed above, to describe the type of information transferred, its nature and scope.

Table 1: Measures of information flow

	Index	Description	Symbol
(a)	Acts Frequency	Examine the frequency of usage of a project's information packages	AFr
(b)	Information Package Size	Examine and quantify the level of detail of information packages	IPS
(c)	Batch Size	Describe the volume of information batch transferred	BSz
(d)	Batch Rhythm	Describe the rhythm in which the information batches transferred	BRy
(e)	Turbulence	Define the nature of the flow	Tur
(f)	Information Development Velocity	Define the speed and rate of information expansion	IDV
(g)	Rework	Examine the amount and nature of designers rework	Rew
(h)	Bottlenecks	Define weakest work station in the process	Bot

Activity Frequency

The activity frequency index describes the frequency of usage of a project's information packages, i.e. the rate at which information transfer and information treatment events take place. Alternatively, we can say that the index describes the frequency with which any processing activity (viewing, loading, presentation, erasure, update, attachment, etc.) takes place for information packages (drafting files, meeting summaries, presentations, bills of quantity, building information modelling (BIM) type objects, and so on).

Even though the information development process may be continuous within each design office, taking place over time, the information accumulated has no utility for the rest of the team until it is made available to others. It can be considered to be hidden and inapplicable. Only when information is made available to all those requiring it, does it obtain value and provide benefit to the entire project.

Due to the nature of the tools and practices common in the process of civil engineering design, information packages are usually transferred in batches, their content and completeness varying from batch to batch. The optimum values for the size of batches and the frequency of their publication depend, to a large extent, on the type of project, the number of designers involved, and the way the project is managed. The number of ways of grouping information in batches in a project is essentially unlimited. The sorting method and the choice of batch criteria have a considerable influence on the behaviour of the index and accordingly on the conclusions reached from its analysis.

$NOA_{i,j}$ - Total number of actions carried out on the information batches on day i in batch j

TTP_j - Total time period in which measured j batch (days)

NOS_j - Number of sections into which the total time period of j batch is divided

Index Sensitivity $$S_j = \frac{TTP_j}{NOS_j}$$

Actions Frequency in batch j on day i $$AFr_{i,j} = \sum_{i=-S}^{S} \frac{NOA_{i,j}}{2S+1}$$

Average actions Frequency in batch j on day i [act\day] $$\overline{AFr}_j = \sum_{i=S+1}^{n-S-1} \frac{AFr_{i,j}}{n-2S}$$

The standard deviation will be used as a statistical index for describing the scattering of values of a data group around their average.

Standard deviation of actions frequency in batch j $$\sigma_j = \pm\sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(AFr_{i,j} - \overline{AFr}_j\right)^2}$$

Information Package Size

The information package size index is intended to examine and quantify the level of detail of information packages, and to allow comparison to the total number of items in order to demonstrate the level of completeness of packages of transferred material. It would be convenient to use an automated count such as the physical size of the information package (number of words, number of graphic objects, number of dimensions, file size in kB, or similar), but these do not accurately reflect the information content of a package. A change in the physical size of an information package doesn't necessarily result in addition or reduction to the scope of transferred information. In addition, occasionally reducing the package size embodies positive design progress and vice versa. For this reason, the index is based on counting information units. The index can be formulated on two levels of detail: by counting the number of information objects in an information package, or by counting the number of information items in the package.

The package size can be used to monitor the pace of accumulation of new information in either relative or absolute terms. In relative terms, the information package size can be compared with the size of an earlier version of the same package to determine a percent increase. However, if a measure of the completeness of a package is needed, an absolute measure can be used, but this can only be done if the final required information package size can be estimated. A final size might be set using specific sampling of archived packages, by estimating the maturity of the package at any stage, or by careful planning the information content required for each package.

Where the same information objects are reflected in multiple information packages, the count of information items across packages may be misleading, reflecting increasing package size where in fact it is only the same information being recorded more times. Thus the index may show growth even when no real information is being added. One way to avoid this pitfall is to select a small number of representative packages for measurement instead of using all of the packages. For example, for a building, floor plans can be used while sections and elevations are excluded.

Batch Size

Efficient information transfer isn't necessarily dependent on the size of an individual information package or on the effective number of information unit (objects or items) it contains. Sometimes, the need to transfer complete and comprehensive information on the one hand, or to focus on a narrow subject on the other hand, determines the volume of the transfer, the efficiency of the transfer and as a result the value added to the project.

The batch size index is a quantitative and qualitative index intended to describe the volume of information transferred by an individual designer or consultant in a single, short and sealed pulse. This reflects the quantity of information accumulated by that participant in the time period since their previous delivery of information. The index is also used to quantify and examine the number of information packages that the batch contains. In a similar manner to the information package index, the batch size index can be formulated on two levels of detail, i.e. the number of information *objects* or the number of information *items* transferred in each batch.

Batch Rhythm

Measuring the rhythm of the batches is intended to show another facet of project information flow. By identification of the project events dates, measuring the total number of actions that were carried out between those events, calculating frequencies of batches and tracing anomalies in their appearances, it is possible to measure this index. On the one hand, the rhythm of the information transfer patterns may shed light on the performance of the project team, its efficiency and dedication to the project. On the other hand, they may give an indication of how the developer and project manager function, and the maturity of the project plans.

An analysis of the harmony of information package movement may shed light on the activities of the team members, the correlation between providing and using internal project information and the influence of external interference. Disharmonic activities may be an indication of failures in their execution, indicating those responsible and possible directions for improvement.

Turbulence
Turbulent flow is defined in fluid mechanics as the motion of a fluid whose velocity at any point along the flow line fluctuates at an unsteady rate and in an irregular fashion. This is in contrast to laminar flow, where the fluid is considered as consisting of many very thin layers, moving parallel to one another, at a uniform velocity, uniform rate and within a uniform flow direction. In order to determine the nature of the flow in a typical cross-section, use is made of a Reynolds number. By computing the ratio of the fluid's inertial forces to the frictional forces acting between the fluid and it's surroundings and comparing them to known values, one can determine if the flow is turbulent or laminar.

In a similar fashion (Fyall 2002) information flow can be characterized and defined using parameters describing the velocity of material transfer, type of typical project, wealth of information inherent in the information package, number of package versions, etc. Examining information flow paths, calculating the turbulence index and comparing the results to known values will assist in defining the nature of the flow and will help set project managers in the right direction.

The evaluation of the turbulence index is based on the calculation of the information density, estimation of the development rate of the information units, and using a constant adjusted to the project type.

Information Development velocity
This measure is calculated by dividing the growth in size of information packages by the time gap over which it occurs. The development velocity characterises designers' behaviour and reveals the information flow paths. It also enables identification of crises when they occur. The index is influenced by the pace of information exposure to the public domain and by the degree of completeness at the time it is calculated. Since it is impossible to calculate the end value of the information precisely at the beginning of the design process, the index's variables were selected in a manner that allows reevaluation during the course of the design process.

Rework
Although to most managers the term "rework" carries negative connotations, it can have value in the design process. The rework measure reveals the amount of rework in the design process and categorizes it according to its origin and contribution to the complete information value measured at the end of the process. It assists in determining the degree of changes made in the design and clarifying their origin. Tracking the sources of rework will allow project manager to find out its causes, control its effects and mange its appearance in order to achieve the best benefit and value to the project.

Bottlenecks
The max-flow min-cut theorem taken from graph theory demonstrates how the maximal amount of flow that can be transferred in a flow network is equal to the minimal capacity of any network cross-section. In an equivalent manner, we can assume that the overall performance of a production system will be limited for the upper production threshold of the weakest work station in the process (Goldratt and Cox 1993; Hopp and Spearman 2001).

In a manufacturing plant, production at full capacity at a production station may lead to the accumulation of inventory in the process at the work station and at the same time to the creation of unnecessary burden on the production station in the upstream flow. Bottlenecks can be detected by examining the production floor and identifying inventory waiting to be processed at the work station.

As explained in the introduction above, the same features of flow, such as bottlenecks, batch size and control are observed in both detailed design processes and production processes. For example, we can identify bottlenecks along the design chain where the team doesn't function for various reasons, or where external workloads on an individual designer prevent progress. Identifying these points by locating unusual information transfer and tracing anomalous behaviour can help managing their causes and assist in smoothing out the process and improving project outcomes.

CONCLUSIONS

The main contribution of this research can be expressed in terms of improvement in multidisciplinary civil engineering project outcomes by promoting understanding of the functioning of the design environment and by instilling practical measures as the basis for better management of all the functions involved in the project. Quantifying measures of information flow is achieved using predefined flow indices. Automating data collection for the indices and creating simple techniques for implementation will make it easier to use the method in the framework of the continuous activities of any project.

In spite of the fact that design management is an important element in influencing project performance, the accepted process planning methods are taken principally from the performance field and are not entirely suited for an essentially iterative process such as design. Using the suggested indices and assistance tools/agents for analyzing and quantifying the value amassing progression along the information flow path, can help design managers deal with the difficulties in planning, controlling and managing the process.

Creating a mechanism to assist in monitoring the influence of abstract processes may cause concern about creating a baseless sense of control of the project among project managers and team members. Yet, a careful use of the suggested model for measuring efficiency of information flow, and finding the correlation between this and the final results of the project, will improve the project outputs and deepen the knowledge and understanding of progress in the design environment altogether. Implementing a management and planning method based on lean management principles and the model may provide an alternative route for planning in the design process, for controlling it in real-time, and for learning lessons which will serve interested parties in the future.

The next stage of the research will deal with validating and calibrating the indices based on their application to the projects and examining their values in relation to the measures of success of the projects. Determining project success will be done by analyzing design control documents, examining time schedules of the project and comparing them to the original time schedule, researching the changes and additions made during the implementation and examining the suitability of the final product to the client's expectations.

In the future, the results of the study might become the basis for the reinforcement or refutation of current concepts for managing an array of consultants and designers, and determining an objective model for value appraisal.

THE VALUE OF CONSTRUCTION MANAGEMENT JOURNALS TO SUBMITTING AUTHORS

Bo-Christer Björk[1] and Jan Bröchner[2]

[2]*Department of Technology Management and Economics, Chalmers University of Technology, SE-41126 Göteborg, Sweden*

Publishers of academic journals can be seen as service providers to authors, in addition to their traditional role of providers of research results to readers. When submitting their manuscripts to journals authors make choices that may have career consequences for them as academics, and they would benefit from better information about the service characteristics of the journals they choose between. The purpose of this study was to analyse author perceptions of leading journals in construction management. Seven journals were identified and for each 2006 article, one author email address was extracted. A web-based questionnaire was sent to 397 authors and 35% responded. It was found that there was a core of three journals, regularly followed by at least half the respondents. These are journals that fulfil the criterion of 'relevant readership', which respondents ranked very high among service characteristics. Most of the other four journals have scopes broader than construction management and receive lower scores for characteristics such as impact on researchers. No open access journals were included, and authors in the field of construction management rarely post openly accessible copies of their manuscripts or publications on the web.

Keywords: authors, journals, open access, readership.

INTRODUCTION

Every time academic authors submit a manuscript to a particular peer reviewed scholarly journal, they are making an important decision which may have repercussions on their future careers. In choosing a particular journal the author is in fact making an investment decision. A bad choice will result in a poor return rate on the time and effort spent on the underlying research; a good choice may enhance reputation and the impact of the research presented in the manuscript. Economists have even calculated the discounted present value of publishing in a prestigious journal, in terms of future higher salaries, which helps explain why academic authors as a rule donate the fruits of their labour to scientific publishers. The fact of the matter is that academics barter their products for services rendered by the publishers. In this regard journal publishers are service providers to authors just as much as content providers to readers. Because of this situation, and because there is no price differentiation between bad and good manuscripts, the competition for good manuscripts is sometimes fierce, as experienced in the proliferation of calls for special issues.

[1] bo-christer.bjork@hanken.fi

In most other situations where consumers or companies face economic choices such as choosing between cars or home cinema equipment they are able to find a lot of data and market comparisons to help them make informed choices. This is not the case in the scientific journal market. How many of us know the number of subscribers or today, more importantly, the size of readership of the journals we submit to? If the publishers are asked for these data they usually regard them as trade secrets, partly motivated by the fear that low numbers would scare potential authors. Equally authors often have only a vague feeling for the rejection rates of journals. The only measurable factors that are well known are whether the journal is indexed by the ISI or not, and if it is, what its impact factor is.

Despite the lack of robust data on the performance of journals the 'invisible colleges' of a particular research field usually have established ranking orders of the journals in the field, whether unofficial or published ones. These are usually based on an assessment of the rigour of the review process of a journal and the academic quality of its papers. Sporadically, there have been studies of construction management journals. A pioneering study of the first decade of articles in *Construction Management and Economics* was published by Betts and Lansley in 1993, who also analysed the *International Journal of Project Management* (Betts and Lansley 1995). Chau (1997) ranked 22 construction management journals based on email responses from the CNBR network. More recently, Pietroforte and Stefani (2004) have analysed contents in articles published in the *ASCE Journal of Construction Engineering and Management*. Recently, Adeli (2007) discussed ISI impact factors for journals in a closely related field, civil and infrastructure engineering research.

Aspects not usually taken into account in traditional rankings are the speed of publication (from submission to publication) and how well the journals are reaching out to practitioners. Such factors can be important in fast-moving fields such as biotechnology or IT.

The purpose of this study is to analyse author perceptions of leading journals in construction management and author attitudes to open access publishing. An email survey with a web questionnaire has been made, and the responses are analysed. Finally, we discuss the outlook for open access and its consequences for construction management authors.

RESEARCH METHOD

Björk *et al*. (2006) have designed a methodology for benchmarking scientific journals from the submitting author's viewpoint. The methodology has been initially tested on construction IT journals and proposes the use of four different data collection methods:

1. Data openly and directly available in printed issues and from the websites of publishers, for instance subscription rates of journals.
2. Data available openly but which need to be calculated. In some journals the submission dates for articles are given in the published articles. From these data the average time from submission to publication can be calculated.
3. Data which can be obtained from publishers. Typical examples would be number of paper issues printed, usage statistics for web downloads.

4. Asking authors about their experiences with journals and perceptions of different journals. This method is excellent for instance to find out about the service level of the journals to authors.

The earlier study by Björk *et al*. (2005) on construction IT journals used methods (1) and (2) above. The present study of journals in the field of construction management and economics relies on the fourth method, asking authors in the field.

Our author-based survey proceeded in several stages. First, the relevant set of journals had to be defined. Initially, four top journals in the field of construction management were chosen: *Construction Management and Economics* (CME); *Journal of Construction Engineering and Management* (JCEM); *Engineering, Construction and Architectural Management* (ECAM); *Building Research and Information* (BRI; in this case, only articles of a CM content). Using Google Scholar for construction management articles in BRI and for all articles in CME and ECAM, while Scopus was relied on for JCEM (where the Google Scholar chronology errs), the five authors for each journal with the most cited articles published 2000–04 were identified. Two of the five most cited CME authors are also among the five most cited ECAM authors; the following two most cited ECAM authors have been brought into the analysis, given a total of 20 authors.

Next, since a main idea of this investigation is to support authors when they are choosing between publication outlets, for each of the 20 authors, their (up to) five other journals with their most cited articles published elsewhere have been identified using Google Scholar and the same time period, 2000–04. All of these authors had not appeared in all five of the other journals, but most of them actually had.

The final criteria for selecting among 41 journals thus identified in addition to the four initially chosen were that at least three of the top five cited authors among the original set of four journals appear with highly cited articles in the journal; the journal should primarily aim at an academic readership; and that construction management should belong to the core area of the journal.

Applying these criteria raises the number of journals from four to seven (see Table 1).

Table 1: Selected journals

Journal	**Publisher**	**Number of articles (2006)**
Automation in Construction (AIC)	Elsevier	65
Building Research and Information (BRI)	Taylor & Francis	44
Construction Innovation (CI)	Emerald	16
Construction Management and Economics (CME)	Taylor & Francis	107
Engineering, Construction and Architectural Management (ECAM)	Emerald	36
International Journal of Project Management (IJPM)	Elsevier	72
Journal of Construction Engineering and Management (JCEM)	ASCE	135

The second stage was the identification of authors. The total number of articles published in 2006 was 475 for the seven journals, and for each article, an email address to the corresponding author was recorded (alternatively the first author with an email address given in the article; exceptionally, when no email address was given, an author email address was located on the web). After deleting multiple occurrences of author names, 397 author addresses were located.

A web questionnaire was designed with 21 questions, including six with five-degree Likert scales. Emails with links to the questionnaire were sent out in February 2007, and after one reminder, a total of 140 answers had been received, corresponding to a 35% response rate. Error messages were received for 8% of the email addresses.

RESULTS

Respondent profiles

The personal information provided by the 140 respondents shows that an overwhelming majority (93%) are university employees, although five respondents are employed by private companies and the remaining five by other organizations outside the university system. Almost half (41%) of respondents in academia are employed in a permanent professorial position, and the same percentage applies to those in untenured positions; in addition, 10% are PhD students. There is a good spread geographically with authors from no fewer than 39 countries being represented; US responses make up 19% of the total, followed by the UK (14%), Australia (8%) and China (7%). In regional terms, both the European continent (4%) and Africa (4%) are comparatively poorly represented.

Readership of journal articles

Respondents were asked about the number of scientific articles they either browse through or read in detail per year. The overwhelming majority browsed through 20–199 articles: 21% browsed through 20–49, 27% 50–99 and 17% 100–199 articles. For full reading the majority of respondents belonged to the 10–99 articles range, where 29% read 10–19, 28% read 20–49 and 21% read 50–99. An earlier study by Björk and Turk (2000) of researchers in construction IT and construction management showed that academics in these fields browse through or read in detail 107 papers per year, which is in accordance with the present results.

However, this can be contrasted with data provided by Tenopir and King (2000), who have made extensive longitudinal studies over multiple research fields. They have found that academics report on average 370 hours per year reading and that university-based academics read on average 188 articles per year. The latter figure is higher than our study shows for construction management authors. There are some possible explanations for this discrepancy. First, Tenopir and King talk of ‘reading going beyond the contents page, title and abstract to the text of the document’, leaving to interpretation whether it is closer to browsing through or reading in detail. The second explanation is that scientific fields differ in their dependence on various publication channels. In some fields publishing is highly concentrated on journal articles, while in others such as construction management conference publishing, monographs and technical reports are frequent.

Criteria for choice of journal

Respondent were asked what relative weight (on a Likert scale of 1–5) they attached to a number of factors when choosing where to submit a manuscript. The results are shown in Table 2. Not surprisingly, ‘high academic status’ receives the highest score (4.5 average). But more interestingly number two on the list, ‘relevant readership’ (4.0) is felt to be much more important than large circulation. Although respondent interpretations of ‘academic status’ and ‘relevance’ may vary, we interpret this as showing that the authors care less about reaching a wide audience than being read by the core CM academic community, where they hope to have an impact on peers with their results. The fact that many authors seem to care little about articles being 'available freely on the web' (2.3), which could increase readership outside the core community, supports this interpretation.

Table 2: Criteria for choice of journal when submitting a paper

Criteria	Average score
High academic status	4.5
Relevant readership	4.0
Journal indexed by the ISI	3.5
Short lead time from submission to publication	3.4
Likelihood of acceptance	3.3
Large circulation	3.2
Level of impact factor (for ISI indexed journals)	3.1
Journal recommendation from author's university	2.9
Journal articles freely available on the web	2.3

Two more pragmatic variables affecting the fate of a submission, namely likelihood of acceptance (3.3) and short lead time from submission to final publication (3.5) seem to matter considerably to authors. Nevertheless, this is where there is usually a lack of available statistics and authors have to rely on word of mouth or guesswork.

Finally the factors immediately connected to the reward systems of universities, tenure, committees, etc., have medium importance on average. These include ISI indexing (3.4), level of impact factors (3.0) and journal recommendation from the author's university (2.9). It is suggestive that ISI indexing as such is deemed more important than the actual level of the journal impact factor, which would be a better indicator of the quality of a journal. This downplaying of the impact factor may have to do with the fact that, in contrast with most other research fields, few of the journals and conferences in which CM authors publish are indexed by the ISI and also that the impact factors of most indexed journals within this field are low, reflecting that there are no clear top journals according to the impact factor criterion. This is unlike research fields such as management science or information systems where top journals with high impact factors have emerged.

Readership and impact of the journals in the sample

When asked about how often they read each of the seven journals identified in the survey, three journals (CME, JCEM and IJPM) emerged as 'core journals' that at least half the respondents follow regularly (Table 3). The other four journals, which also cover topic areas other than the central construction management and economics ones, were less regularly followed and unknown to a higher proportion of authors.

Table 3: Reader habits and impact assessment (% of responding authors)

Variables	AIC	BRI	CI	CME	ECAM	IJPM	JCEM
Not familiar with journal	42	36	49	11	31	19	16
Read regularly or almost regularly	23	23	11	57	28	47	66
Impact on researchers of articles in the journal							
Don't know	*51*	*45*	*57*	*21*	*39*	*28*	*26*
For those who know: High, or almost high (4–5 on the 5-degree scale)	48	46	20	81	49	61	86
Career value of publishing in the journal							
Don't know	*48*	*44*	*54*	*21*	*38*	*27*	*26*
For those who know: High, or almost high (4–5 on the 5-degree scale)	47	49	31	73	55	60	85

Owing to the high proportion of answers revealing a lack of knowledge with the service characteristics of any of the seven journals, the following figures should be treated with caution.

Across journals, there is a broad similarity in the number of respondents who are familiar or unfamiliar with the impact and career value of choosing a particular journal.

Assessing service levels

When respondents assess the level of service offered by a publisher or the helpfulness of the review process for submitted articles, we can assume that opinions are based on their own experiences or those of close colleagues. This is probably why the 'don't know' percentages are higher in Table 4 than in Table 3.

Table 4: Assessments of service level and review process (% of responding authors)

Service level and review process	AIC	BRI	CI	CME	ECAM	IJPM	JCEM
Publisher service level							
Don't know	*67*	*67*	*77*	*33*	*59*	*53*	*41*
For those who know the journal: High, or almost high (4–5 on the 5-degree scale)	52	60	38	79	42	61	57
Helpfulness of review process							
Don't know	*67*	*65*	*78*	*32*	*57*	*48*	*39*
For those who know: High, or almost high (4–5 on the 5-degree scale)	57	57	35	77	48	57	74

Submission rejection risk

According to Table 5, the respondent estimates of the average submission rejection risks were typically concentrated in the 25–50% and 50–75% ranges. A few observations can be made about the results. *Construction Innovation* was deemed to be the easiest journal to get published in with a clear dominance of answers in the <25% and 25–50% ranges. *Building Research and Information* attracted the widest spread of estimates, with 16% of the respondents guessing for less than 25%, while at the other end of the range 11% guessing at a rejection rate in excess of 90%. Guesses for *Construction Management and Economics* were highly concentrated in the 50–75% range. The explanation for this more narrow range might be that CME has made available on its web pages annual statistics for submissions and published articles; it is thus likely that many authors know that the average CME rejection rate has been around 50% for a number of years.

Table 5: Perceived risk of rejection (% of responding authors)

Submission rejection risk	AIC	BRI	CI	CME	ECAM	IJPM	JCEM
Don't know [% of authors]	*73*	*71*	*79*	*48*	*62*	*54*	*48*
For those who think they know:							
<25%	17	16	44	8	16	20	6
25–50%	43	21	30	21	49	33	32
50–75%	29	29	19	57	27	35	37
75–90%	11	24	7	14	6	8	18
>90%	0	10	0	0	2	3	7

Although there are no reliable statistics for scientific journals in general it is worth mentioning that the Director of Strategy of Elsevier, the biggest scientific publisher, recently revealed (Fowler 2007) that they process more than 500 000 submissions per year resulting in more than 200 000 published articles, which amounts to an overall rejection rate of about 60%.

Posting copies of manuscripts or articles openly on the web

There are currently strong demands for changes in the scholarly publishing systems to better take into account the opportunities offered by the Internet. Open Access, as this alternative to the traditional dissemination model is termed, can be achieved in two ways. The first route is that journals themselves start posting the articles totally openly on the web, this being run as an open source like operation with no budgets, or journals recoup their costs by other means than subscriptions, for instance by publishing charges. The *Lean Construction Journal* and the *Journal of Information Technology in Construction* (ITcon) are examples of the former type. The use of author charges is practised in particular by two biomedical publishers, BioMedCentral and Public Library of Science.

The second route is that authors publish in the same journals as usual, but themselves post copies of their manuscripts prior to or after peer review on their own web pages, in the institutional repositories of their universities or in subject-based repositories such as the ITC Digital Library (http://itc.scix.net/) for construction informatics. Contrary to a widespread belief among scientists many publishers allow this practice in their copyright agreements with authors. The Sherpa/Romeo database (http://www.sherpa.ac.uk/romeo.php) contains information about the policies of all major publishers, and according to it a vast majority of journals allow posting of even the final corrected manuscript after peer review but before final publishers' copyediting and layout.

We asked the authors in our survey if they have put up copies of their manuscripts or final versions of conference papers or journal papers on the web. Very few had done so. The most popular location for manuscripts was the author's own home pages where 18% had posted at least one manuscript, and for final publications, the institutional repository of the author, where again 18% had posted at least one publication. It appears that 3% had posted all their manuscripts and also 3% all their final publications openly on the web. These results are in line with broader studies of authorial behaviour in general (JISC 2004), which indicate that open access copies are available for only about 5–10% of all journal articles.

CONCLUSIONS

Our survey results show that researchers who publish scientific articles in the field of construction management do not differ markedly from academic authors in general. They do read slightly fewer articles, and they are little concerned with journal impact factors. Much like in other fields they enjoy being read by a narrow circle of peers. Scientific publishing fills an important role as a reasonably neutral and global system of talent assessment that influences decisions on promotion and tenure in many university cultures. It is possible to detect profiles of CM journals that could be used as a broader base for benchmarking from the viewpoint of authors. This should also be helpful for journal publishers and editors who wish to make their journals more attractive as outlets for research in the field.

From our analysis a cluster of three core journals emerges (CME, IJPM and JCEM). These three are regularly followed by at least half the respondents, which also could indicate that they have personal subscriptions or institutionally paid access to them. Unfortunately only one of these (JCEM) is indexed in the Science Citations Index, which makes citations-based comparisons difficult. The other four journals receive lower scores on readership as well as on some of the other perceived characteristics.

At present, construction management authors rely on open access publishing to about the same extent as authors in other academic fields. The slow convergence of traditional paper-based publishing and digital publishing leads to new patterns and business models.

Although the response rate is high for this type of email survey, bias in favour of email readers is probably something that has to be kept in mind when interpreting the results. Thus our responses might overstate the proportion of authors who actually post their texts on the web.

ACKNOWLEDGEMENTS

We would like to thank all participants in the web-based survey, some of whom also separately provided encouragement by emailing us. We would also in particular like to thank Patrik Welling, who helped in setting up the technical part of the survey.

WHO READS *CONSTRUCTION MANAGEMENT AND ECONOMICS* AND WHY?

David Seymour[1]

School of Engineering, University of Birmingham, Edgbaston, Birmingham, B15 2TT, UK

Taking the latest issue (at time of writing) of *CME*, the 23 articles it contains are examined. It is proposed that 11 of them can usefully be thought of as narratives that describe a context in such a way as to instruct the reader on how the particulars reported in the study are to be understood. A second set of papers describes tools, techniques or methods designed to contribute directly to industry practice. A sample of the papers are discussed in detail with reference to the questions: to whom is the research addressed with what purpose, how success in achieving that purpose is judged and what other criteria for success might be considered. The conclusion is that the research reported is primarily read by other researchers. Three reasons are offered for why they are read: first, in the expectation that the research tells of innovations and developments that might be applied in practice, 'practice' understood to include the concerns of site operatives through to national governments; second, in the expectation simply of learning things that were not known before about the construction industry worldwide; and third, and most importantly, because readers look for stories that make more sense than the ones they already know, concerning themes of which they are already aware and to which they wish to contribute. On the assumption that the conclusion is correct, suggestions are made as to: (i) ways of ensuring that topics which are researched address practitioner interests and concerns; and (ii) ways of ensuring that they *are* addressed are made an intrinsic part of the research process.

Keywords: communication, narrative, research, practice.

INTRODUCTION

The title of this paper expresses questions to which I don't know the answer. I have my guesses, which I can best begin to explain by citing Stephen Holmes' review of Francis Fukuyama's new book (Holmes 2006: 13). This book is a follow-up to his story – set out in 'The end of history and the last man' – which was that with the fall of communism we find ourselves in a capitalist paradise. The events of 9/11 have given him cause to think again, hence the new book and a new story.

"The question is: [writes Holmes] does Fukuyama tell us anything we don't already know? Can he explain how 'the irresponsible exercise of American power' became 'one of the chief problems of contemporary politics'? Can he help us understand how 'so experienced a foreign policy team' could make 'such elementary blunders'? Can he indeed tell us why the administration decided to do what he and his former allies had encouraged them to do […]?"

I highlight the words: "tell us", "explain" and "help us understand" "what […] to do" and will draw some parallels with construction management research. "Tell us" implies information about a new method or technique; that a piece of research has

[1] d.e.seymour@bham.ac.uk

found out something that was not known before; that it provides factual information about a given state of affairs; remedies mere impressions and guesses or claims to show that what was thought to be known is wrong. “Explain” implies connectedness; associating things and events, perhaps causally, not noticed before or challenging received explanations. “Help us understand” implies both of the above but more modestly providing some kind of narrative, a story that makes sense; pulls together previously (for us) disparate information and impressions. All of them, either explicitly or implicitly address the question: so what do we do? This last, in Fukuyama’s case, a matter of encouraging the administration to do things for which he is now bringing them to book.

I began with the reference to Fukuyama because he has provided a dramatic instance of the apparent need people have for some kind of narrative, a story that sets all in order, the better if it gives grounds for optimism, hope that positive change is feasible. It seems to me that most of the contributions to *CME* have this objective. With the view to testing this hunch and with Holmes’ questions in mind, I reviewed the 23 contributions to the April–June 2006 issue of the journal (the most recent to hand), assuming that it would be adequately representative of what is on offer.

Ten of them, as I will try to show in Section 2, aim to tell a story. Though not as weighty as the global politics addressed by Fukuyama, they have a similar purpose: to describe a state of affairs from a claimed position of academic detachment. Usually, the authors attempt to justify their claim to objectivity in a methodology section. Sometimes they say what their purposes are, sometimes who the story is intended for, why they should listen and what the moral of the story is. I will consider each of them in turn. In Section 3, I will consider seven further stories whose purpose is different, namely, to describe a tool, method or technique designed to improve financial and contract management practices that are claimed to be useful to industry practitioners; then another five that are about tools or methods designed to improve performance on a range of important and necessary tasks. In Section 4, I consider the final paper, which provides both the description of a tool and a story with very interesting results. In the concluding section I will suggest ways of ensuring that topics which are researched address practitioner interests and concerns, and ways of confirming that they *are* addressed are made an intrinsic part of the research process.

STORIES AND CONTEXTS

I call this section ‘Stories and Contexts’ because the main purpose of the papers reviewed here is to provide some kind of overview, to characterize a context in such a way as to have us understand particular instances (phenomena and events) in a particular way. There has long been an interest in stories as cultural products since they have much to tell us about social organization. For example, ‘moral tales’, are used to inculcate the values and norms of a given society. More subtly, an action plan, a strategy statement and other artefacts can also be seen as a kind of story, detailing, for example, what has to be done. However, fairly recently the fact that *reporting research* into social organization can itself be seen as story telling has also become of interest. Challenging the representationalist conception of language (that it can be used to describe what is really ‘out there’), the ontological status of concepts like ‘organization’ or ‘culture’ become problematic. Thus, by what *cultural processes* do such concepts acquire apparently concrete status “as already constituted entit[ies]?” (Chia 1996: 583). The position adopted in this paper is that in highlighting these *cultural processes* by which words acquire the meaning they do, it becomes apparent that there are (for our purposes here) two distinct milieus in which the processes occur: construction industry organizational practice and the *reporting* of that practice by academic researchers.

In the former, there are stories that have a clear practical purpose, enabling people to communicate intentions, understand what other people are doing, learn what the rules are, what happens to deviants and so on, making possible shared, or at least negotiated, definitions of the situation and thus orderly social interaction.

The milieus for *reporting* industry practice are journals like *CME*, academic conferences and sometimes industry workshops or seminars where practitioners are addressed. All of these are settings subject to their own rules and conventions. The questions I raise are: how does what goes on in these milieus relate to each other, and how do the stories that are produced within them relate to each other? Putting it slightly differently, how do the ways researchers contextualize what they report relate to the contexts that practitioners take for granted as existing? If, following the line of reasoning offered by Chia and others, they are all cultural constructions, simply different versions or stories, what then? This is especially important when, as we will see in some of the papers considered, researchers *contradict* practitioners, claiming to know more or better than they do.

To begin with Caven, she tells a story about the careers of women in architecture based on interviews with a sample of them, some of whom are allowed to speak for themselves for illustrative purposes. Its aim is generally to persuade readers of the truth of the story she tells and also to promote the interests of women in the job market. Citing several commentators who have asserted that "the construction industry has historically not appealed to women as it is perceived as being physically demanding, combative and male dominated" (p. 457 – all page references given, unless indication to the contrary, refer to *Construction Management and Economics*, **24**(4–6), 2006), she gives some statistics to support their story and proceeds to use it as a backdrop or context for the story she is about to tell. There is nothing wrong in any of this. What I am highlighting is the fact that such a context is offered as real, in the sense that since a number of experts have described it as such and in the absence of accounts to the contrary, it may be accepted as a true account of the way things really are. This is not to say I don't believe it. In fact, with respect to the UK with which I have some experience, I do. But of course, the description is a cultural construct, a story – no more nor less – reflecting the concerns, interests, understandings and meanings of the person who provides it in a setting or milieu in which s/he has reason to provide it.

Styhre and Josephson tell a story about middle managers on construction sites that is intended to challenge the received story. They too allow people to speak for themselves. They advocate, presumably to those in the industry who can remedy the situation, a more positive image of these managers. The reason they are telling the story of what they have found out, which (again) I have no reason for doubting, has explicit reference to other stories i.e. those that proclaim that middle managers are redundant. It is these which provide the context for Styhre and Josephson's story.

A story about partnering is told by Phua. She rejects the alleged cynicism of Bresnen and Marshall (p. 615) arguing that theirs and most other accounts are based on restricted case studies and that what is required is "large scale cross-sectional studies to examine the relationship between [partnering's] ubiquity and corresponding impacts" (p. 615), i.e. the 'big picture' or a fuller story. She reports a study designed to provide it. With findings from a postal questionnaire survey, her conclusions are not in fact much different from Bresnen and Marshall's – that 'institutional norms', for which I read 'existing culture(s)' have a conservative effect on take-up. She is also at one with them in trying to operationalize 'industry norms' and 'partnering', treating them as finite entities to establish causal relationships between them, ignoring Chia's point that the ontological status of these terms is such that they cannot refer to finite entities. She differs, however, in that she departs entirely from actual decision-making practice which Bresnen and Marshall try to keep in sight, relying on the statistical manipulation of data derived from a fixed-choice questionnaire survey, stimulating extreme doubt about its ability to reflect the variety and complexity of the processes to which these words (i.e. 'industry norms' and 'partnering') refer. Thus, I submit, this story can have no special status as being truer or better than another. It is a matter of believe it if you want to; be persuaded by the evidence offered in support of it, but wait for the next study which, contrary to what Phua has found, may claim to show that it is "decisions grounded in financial inducements" (p. 622), which is the main determinant and not 'institutional norms. How one actually distinguishes 'industry norms' and 'decisions grounded in financial inducements' is another question.

The story by Kale and Arditi is about the diffusion of ISO 9000 to Turkey. It uses the theoretical framework provided in the Population Ecology approach of DiMaggio and Powell (1983) and others, which posits an ever-expanding set of rationalized organizational models and ideologies, such as ISO 9000, which organizations throughout the globe variously try to imitate and incorporate. Though DiMaggio's and Powell's approach acknowledges that these attempts may be merely ritualistic or used opportunistically with little practical outcome relative to overt objectives, nonetheless their approach precisely formalizes out of view the intricate processes involved in particular settings where management systems like ISO 9000 are introduced.

We meet the same problem that we saw with Phua, trying clearly to identify a variable that impacts on other variables. Thus, Kale and Arditi assume that there is a finite set of practices found in economically advanced countries that constitute the application of ISO 9000 (and note, not the prescriptions contained in the ISO 9000 documentation itself) and it is this (thing) that is being imitated. However, as with partnering, there are a multitude of practices which pass as 'being Quality Assured' despite the certification procedures that ISO 9000 imposes. So, what exactly is it that imitating firms are supposed to be imitating? Certainly not the ideational construct identified as ISO 9000 by Kale and Arditi for the purposes of their model, rather, a range of practices that can only be found out by a close study of those practices in the settings where they are employed. Second, suppose they are imitating something, why are they imitating it? Kale and Arditi say that there are three possible reasons: (i) internal, i.e. in pursuit of rational efficiency and because other firms are doing it; (ii) external, i.e. influences from e.g. government regulation or client requirements; (iii) mixed, i.e. a combination of both the above. The first comment is that Kale and Arditi's conclusions, i.e. the story told about firms in Turkey as to what they are doing and why, is that by restricting the kinds of reasons on offer it ignores others that might be at work (the same problem noted with Phua above). Second, it is ethnocentric. It supplies rationales that might be expected in a Western, developed economy, again failing to disclose rationales that might be present in Turkey. Third, it ignores the processes through which action in the name of ISO 9000 is understood, interpreted, challenged, validated and evolves in Turkey or anywhere else.

An anthropological study of a company in Sudan by Rottenburg (1995) directly addresses Population Ecology theory and shows its distortive effects. He argues that its use confuses efficiency with legitimacy since they are so thoroughly conflated in western industrial societies. However, he argues, reminding us of Max Weber's warning on precisely this point, that even in the West, the public justification for an organizational format may be efficiency, but, that format is just as likely to be adopted because it legitimates what goes on "behind the façade" whether efficient or not. In, what Rottenburg calls, "peripheral countries" the justification is more likely to be the latter whilst behind the protective façade any number of practices grounded in other legitimating frameworks may be in operation, obligations to religion, kinship and friendship, for example, which are selectively invoked as the situation requires. Thus, people in a given setting have their own stories about what is going on and it is these stories that inform what they actually do. It is these stories that need to be listened to and understood if we are to find out what is going on the better to understand the intricate dynamics of organizational change and technology transfer. Thus, he presents a complex picture where members of the Sudanese company tactically invoke competing legitimacy discourses, some provided locally and some from a global repertoire, depending on the particular setting and their purposes in it. All this is lost by imposing the explanatory model that Kale and Arditi use.

Liu and Fang tell a story about leaders on Chinese construction projects, apparently not having consulted any of them and this is the point. By aggregating information provided via a questionnaire survey, the authors assume that it is possible to access generic forces at work and that by doing so they can find out something about the dynamics of leadership that any given leader does not know. I suppose Liu and Fang might concede that any given leader may arrive at the same conclusions as they do, conclusions that are verifiably correct through their scientific study. They confess that a lot more work needs to be done to test the validity of their finding but imply that it can be done (p. 505). I suspect, however, that no matter how much more is done, it will just increase the complications and the need for more caveats. In short, their truth claim as to the dynamics of leadership cannot be settled by appealing to 'facts' characterized within a discourse, which provides the context for their study. This is so because it is not the discourse through which the phenomenon itself (i.e. leadership) is constituted in the everyday reality of construction projects. That is, we recognize leadership in the first place in the everyday world in which it is enacted. Thus, though Liu and Fang may characterize leadership within a particular discourse that is different from the way it is characterized in the everyday discourse of a construction site, there is no difficulty "in agreeing that there are persons recognizable as [leaders]. It is this agreement – agreement as to the fundamental ordered existence of the phenomenon independent of it having been addressed by *some* method of enquiry – that [Liu and Fang and people on construction sites] are mutually orientated to a common factual domain" (Zimmerman and Pollner 1971: 81).

In referencing Foucault, they invite another comment that bears on the same matter. Foucault advises that power, which is central to Liu and Fang's theory of leadership, is not to be thought of as a force that can be stood back from and observed as they seem to assume. It exists in the very language we use to characterize human experience. In modern prisons, he suggests (Foucault 1975), disciplining is not experienced as repression but as the necessary condition of the productive work in which prisoners are required to engage and which they accept. Institutional power is so complete that they repress themselves. One need not accept the full implications of what Foucault is saying, i.e. that prisoners are duped into accepting a discourse such that they see repression as discipline. It might be that they accede to the use of the discourse for tactical reasons of their own (like Ronnie Barker in Porridge!) knowing perfectly well what they are required to think. However, what Foucault powerfully highlights is that we conduct our lives in terms of versions of what reality consists of. Whether some versions or discourses *succeed* in excluding or marginalizing others is an empirical question. It would seem to follow, therefore, that if we are to understand leadership in construction we do well to attend to the way people characterize it and its effects *there*. A fixed-choice questionnaire schedule pre-empts our understanding of the way stories of leadership together with a range of other communicative devices are used to confirm the existence of leaders, how you recognize them as leaders and so on. Following Foucault, the discourse that Liu and Fang use to have us understand what leadership 'really' consists in, could be seen as an attempt to assert the power of researchers over practitioners! I return to this point later.

Ramsran and Hosein's story about Trinidad and Tobago is simply intended to inform, presenting findings from various statistical sources, pointing out the public policy implications which they see. Also using various statistical sources, Duncan, Phillips and Prus relate a story about contractors' response to the Government Fair Wage Policy in British Columbia. This paper also seems intended to inform and thereby influence public policy. Sources where further information can be found are usefully given. Thus, both assume familiarity with a common discourse as between providers of the story and those who read it. Readers are invited to take at face value the information provided. If we wish to, we may query their sources, how the statistics were generated and look for a different story – take it or leave it. The assumed context is that constructed by the kinds of information with which we are all familiar, global statistical accounts of this or that phenomenon.

Song, Liu and Langston's paper similarly concerns the provision of a global account, this time of the "construction sector" (p. 579). However, they seem equally divided between recommending the use of an economics technique and telling the story of what its application to construction reveals. Thus, the paper might also be considered under the heading of a tool whose usefulness to practitioners is demonstrated by what it tells us about the construction sector that we didn't know before.

Using data from company web sites and annual reports, Chang, Chou and Wang's story concerns corporate governance of UK construction companies. They are found to compare badly with 'top companies'. While it is never actually stated, the moral of the story seems to be that construction 'should do better' because "'it helps investors exercise their voting rights, raise managerial consciousness [pressurize] managers to fulfil their fiduciary duties" (p. 653). It is not made clear whether that is the purpose nor whom it is addressed to. Presumably, like the previous paper, it is thought to be of interest to anybody who has a use for the information it provides.

Johnson, Lizarralde and Davidson, with reference to two case studies and using a 'systems approach' (p. 369), tell the story about what happened regarding the provision of temporary housing following natural disasters and what can be learnt from them. Emphasizing the importance of organization design, the paper is addressed to people for whom such learning would be relevant. This paper also might be thought of as the recommendation of a tool – 'the systems approach'. However, what distinguishes it from Stewart and Stephens' (considered below) is that the story is not about how the tool was used but how it might have been used in the two cases considered. The context of the paper is the variously reported inadequacies of dealing with the aftermaths of natural disasters.

I have argued that all these stories should be seen as attempts to persuade or intervene and that the relationship with the intended ‘persuadee’ and the warrant for the attempt should be made clear. In all cases, one just submits to being informed or takes them with a pinch of salt depending how one is disposed. However, I suggest that in all cases, one is implicitly invited to test the truth of what is being told against some anonymous set of abstract criteria supposed to reside with some adjudicating body, presumably the community of construction management researchers, rather than the people about whom the various stories are told.

TOOLS, METHODS AND TECHNIQUES

Eight contributions are about methods, techniques and tools designed to improve financial and contract management practices. In all cases, the form of the research is similar. Justification for a new or better tool, technique or method is given. What it consists of and how it was developed are described. In some instances, this involved the collaboration of an industry partner. In others, it was based on data gathered from questionnaire surveys. An example of the former is Tang, Wong Leung and Lam’s tool for making loan decisions. It is not clear, but the study seems to have been a form of action research. Thus, it was simply taken for granted that it would be useful to develop a more reliable tool. Use of the tool is said to have been a success and that with appropriate adjustments it would have generic application. Cheung and Skitmore have developed a tool to help forecasters develop and evaluate their own cost models. This, they say, is “likely to be well received in practice” (p. 401). Wong and Hui identify risk factors that might affect tender price results that, they say, will be beneficial to employers and contractors. Thomas, Kalidindi and Ganesh’s risk probability and impact assessment framework is claimed to “provide insight into the various factors influencing events and their inter-relationships” (p. 420). Papers by Huang and Chou, Zhang and Yang, Yiu and Tam, and Cheah and Liu follow similar formats.

These are all interventions designed to influence and contribute to an ameliorization of industry practice, and are to be welcomed insofar as they do. However, I think it would be useful to know more about the way these products came to market and how, in addition to describing the product, the development process was managed. This might give genuine insight into the relationship between researchers and practitioners that we seem to know so little about. Recognizing space limitations in the journal, perhaps a brief product description and applications should be given and interested parties be referred to a website where more detailed information is available. This would serve the useful purpose of helping to answer the questions addressed in the title of this paper.

Turning to methods having other applications, Hyari and El-Rayes report on how to design effective lighting systems for road projects; Best and Langston on alternative methods for comparing construction performance cross-nationally; Hartmann on detecting factors that would influence the implementation of an innovative idea. Again, these are to be placed in the ‘take it or leave it’ category. The contexts that they assume in writing these articles may (or may not) be recognized and seen as relevant to the concerns of practitioners and acted upon.

Soetanto, Dainty, Glass and Price advise on how to improve group decision making processes, Navon and Berkovich on a materials management and control system. The former is intended to “help the professional disciplines in particular to improve service to their clients” (p. 612). Further research is advised to find out if it does or not. The latter assert that their system has been tested in the field with positive results and that further testing is under way.

While there is some attempt to specify whom recommendations are aimed at (e.g. Hartmann “relevant to researchers and practitioners”), there is little sense that these studies are rooted in the realities of the construction industry, what practitioners might have to say about them, how what is recommended relates to current practice, what problems there might be in implementation and so on. Regarding these issues, most of them seem to offer some under-examined variant of ‘it’s a cultural thing’. That is, the prime interest seems to be in some abstracted vision of construction practice where solutions to the problems experienced there can be solved ‘in principle’ by those at a salutary distance from them.

The final paper examined here, that by Stewart and Spencer, to an admirable extent is exempted from the preceding comment. This is achieved in an interesting way. It is explicitly an intervention and both describes a tool, six-sigma, and tells a story of its application in a case study. It is firmly rooted in on-site experience. The story has two objectives to “describe the application of the six-sigma method on a construction project’ and to evaluate its effectiveness” (p. 342). (The comments on Stewart and Spencer’s paper are influenced by an as yet unpublished analysis by John Rooke, which I have been privileged to read, where he points out the relevance of the Unique Adequacy criterion.)

The authors succeed in documenting how the method is used, how it figures in the on-site discourse. Thus, “firstly, the decisions made and their outcomes for two PIP’s [Project Improvement Projects] were recorded under the five stages of six-sigma philosophy”. For example, they show what went on in the constructability workshop, which was attended by the relevant construction personnel and “the improvement team” (p. 344). Six of the people involved were then interviewed as to their perceptions of the application of six-sigma and other TQM techniques. Apart from, presumably conducting the interviews it is not clear how actively involved the researchers were in the application.

Their story is clearly about what happened, the context being the industry-wide discussion of the practices that are intended to improve quality and efficiency. However, by virtue of the fact that it documents the use of a method germane to that setting, it attends to a *story* which is actively used in the setting, that story being – “do the following things and this is what happens”. That is, they show how the method (six-sigma) that participants in the setting used figures in organizing the social processes that occurred in that setting. Thus, the authors do not *import* a theory and vocabulary with which to tell their story, as do the other stories considered above. Their story, in the telling, displays a discourse used in that setting.

Nonetheless, finally they do implicitly abandon this genuinely objective and non-judgemental stance. Thus, they dismiss out of hand some of the observations of site members elicited during interviews. The respondents’ view was that “six-sigma mainly improved efficiency”. They comment that this “a common misconception about the concept of ‘quality’ and its relationship to the whole production process” (p. 346). In doing this, they address themselves to a wider context as understood by some wider community of which they see themselves part. This membership distinguishes them from those on site. It would be useful to know if their observation on this matter was discussed with site personnel serving to illuminate the relationship between academic and practitioner discourses, which, the present paper has argued, is routinely ignored.

CONCLUSIONS

My guess, then, about ‘who reads *CME* and why?’ is that the research reported in it is primarily read by other researchers. They may well pass on what they find out to students *en route* to becoming practitioners or to active practitioners with whom they have dealings. They may well be wholly or in part practitioners themselves. However, the more interesting question is why? Apart from just finding out what’s new, I think there are three reasons: first, the expectation that the research tells of innovations and developments that *might* be applied in practice, ‘practice’ understood to include the concerns of site operatives through to national governments; second, in the expectation simply of learning things that they didn’t know before, about, say, the construction industry in Trinidad and Tobago; third, and I think most importantly, they look for stories that make more sense than the ones they already know about themes they are already aware of and to which they wish to contribute better understanding. (I take it as read that there is a fourth reason for reading the Journal; that its content needs to be addressed by academics wishing to publish themselves and that there is pressure on them to do. To have taken up this issue would have raised many interesting questions about the institutional relations between the academic and construction industries. As important as they are, it was not my purpose to discuss them.)

If my guess is right, it is the assumed nature of this contribution that seems to be important. I began with the idea of the big picture that provides a context for understanding; a story that seems to offer a coherent account of why the social world is as it is. Such stories seem to get below the confusion of what goes on to provide an account that makes sense of it all. The contributions considered here as stories look to contribute to telling or retelling a story, adding to it, modifying or challenging it, confirming or disconfirming this or that feature of it. I have suggested that they be thought of as interventions, looking to influence what practitioners in the industry do and how they think. This is even more explicit in contributions regarding tools, methods and techniques. It is taken for granted in all cases that the main beneficiaries are industry practitioners, though in most cases I see little concrete evidence of this. Other beneficiaries are sometimes acknowledged; other researchers who are assumed to feed back directly into practice in ways noted in the preceding paragraph. But I think the dominant assumption is that research is ‘its own thing’, what Alfred Schutz calls “a finite province of meaning” with its own ways of conceptualizing issues, “its own cognitive style”, “its own specific accent of reality” (Schutz 1972: 232). Such reports that are produced within it are for others who share it, not for those whom the reports are allegedly about – construction practitioners. The latter’s frame of reference or their context is “the paramount reality” (Schutz 1972: 232) of the everyday world of construction. Thus, for example Stewart and Stephens, as noted above, participate in this everyday world in the application of six-sigma but then withdraw from it into the finite province of meaning shared by other researchers. In turn, they presume that from within it come reports that practitioners, who do not share it, should listen to on account of their greater accuracy, lack of bias and so on. In other words, Stewart and

Stephens shift from participating in a setting in which different viewpoints might be exchanged, to commenting on the setting from a position of assumed superior knowledge. In effect, they enter into discussion with a community of researchers who licence themselves to make such comments.

This is not to say that researchers may not know something that practitioners don't. The point is they need to communicate it; enter into a dialogue with those to whom this knowledge is supposed to be of value in the paramount reality of the everyday world. For this reason, and re-asserting my contention that all research in construction management is tacitly intervention of some kind, the criteria for judging its worth is to be found in the setting where research is actually done, taking into account the reasons for doing it. This implies that outcomes, the 'fitness for purpose' of what is found out, be given equal weight to justifying truth claims. Action research provides such criteria (e.g. Greenwood and Levin 1998; Bray *et al*. 2000), which are based on the assumption that such research is a collaboration between researchers and researched in the real world where, only there, can be found evidence as to its truth and usefulness.

Construction management (CM) is a relatively new discipline that has been expanding its domain of knowledge over the years. The presented study aims at tracing such an evolution by analysing the content of a leading academic journal, *Construction Management and Economics* (CME), namely its abstracts and keywords over a 24-year period, from 1983 to 2006. The content was classified according to a set of subjects and related topics, as well as the institutional sources of contribution. CM, as described in CME, is still an evolving body of knowledge with the inclusion of many new dimensions since 1983. Over the years contributors have shifted their interest towards the management of firms and away from that of projects. These two subjects are addressed more from the theoretical than the practical viewpoint.

Keywords: abstracts, bibliometric study, classification criteria, construction economics, construction management.

INTRODUCTION

This contribution was prompted by the upcoming 25th anniversary of *Construction Management and Economics*, a leading academic journal. The study aims at tracing the evolution of the journal over the years through the analysis of its content since its inception. Construction management (CM) encompasses a relatively new body of knowledge, if compared with the history of construction. Its first appearance in the USA was driven by a variety of challenges that afflicted the construction industry in the 1960s, namely the growing dissatisfaction of clients with the outcome of their investments and the traditional contracting system, the increasing design and construction complexity of projects and the weakening coordination capabilities of design professionals, to name some of the problems. In the late 1960s CM-related programmes started being offered by US civil engineering departments, followed by UK schools in Europe. Over the next 15 years CM's core of knowledge, originally drawn mainly from operations research, expanded and acquired its autonomous features and also emerged as a distinctive field of academic enquiry. The early 1980s, in fact, saw the establishment of the first peer-reviewed journals fully dedicated to the CM field. Since then CM has established itself as a research area that builds upon a long series of publications of scholarly work and debate. Academic journals within any specific discipline play a vital role because they are the primary means for communicating and exchanging research experience. Research or scholarly activities, at the same time, influence the teaching of a discipline and, over the years, the shaping

[1] roberto@wpi.edu

of educational programmes at large. As addressed by Betts and Lansley (1993), higher education provides the cultural capital and nourishment for the sustainability of professionalization and at the same time the addition of new knowledge, which influences the development of a profession, is likely to be traced in the academic journals. Typical examples are the arrays of periodicals that have sustained the architectural and structural engineering professions over the years. This type of reasoning, unfortunately, is more difficult to apply to CM in both professional and educational terms. In contrast to architectural and structural engineering practices, the responsibilities of CM activities are allocated differently around the world and, considering its interdisciplinary nature, it is difficult to consider CM as a distinctive discipline.

Furthermore the practice of CM can be considered more as a role than as a profession like that of architects or structural engineers. Depending on a given social, institutional and cultural context, in fact, CM assumes differing characteristics in terms of meaning, range of pertaining subjects and practice. In the USA CM is strongly associated with the American Society of Civil Engineers and its educational institutions. In this regard, academic programmes have a strong technical and technological content, but in practice most of the CM services are offered by construction firms and not professional engineering firms. In the UK and countries of the British Commonwealth, CM is associated with the professional institutions of surveying. In this regard, the domain of CM has a strong economic component (re: construction economics) that is a natural expression of the traditional cost advisory role played by professional surveyors. This profession is significantly involved with CM services, particularly project management, and has been the main development source of construction economics as a discipline distinct from ‘orthodox’ economics. In contrast, in Italy and other European countries CM is associated with the schools of industrial engineering and it has a weak affiliation with professional institutions. Similarly to the USA, most of the CM services are offered by construction firms.

In the past many academic journals have been the subject of bibliometric studies. In the case of CM, the content of journals concerned with construction-related research issues was investigated to provide a partial map of the discipline of construction management and project management (Betts and Lansley 1993 and 1995). More recently, the perspectives on construction research were addressed in terms of challenges of US academic communities (Chinowsky and Diekmann 2004). This paper contains additional results of an ongoing investigation aimed at assessing the past and possible future developments within the CM discipline as it is represented in the US and European academic journals (Pietroforte and Stefani 2004; Pietroforte and Aboullezz 2005). The study considers the papers published by *Construction Management and Economics* (CME) during a 24-year period, from 1983 to 2006. More than 1150 abstracts were analysed from two main perspectives: the type of subject (based on a 12-item list) and topic (from a list of more than 100) that makes up each subject.

The paper initially presents some essential information about the academic journal, including a brief historical introduction, its objectives and key statistical data. Afterwards the methodology for data gathering and the classification criteria, according to which the journal’s content was analysed, are addressed. The disciplinary (or institutional) sources of contributions are analysed. The last part of the paper outlines the breakdown of the papers’ focus in terms of CM and construction economics subjects as well as their component topics.

HISTORY AND STATISTICAL DATA OF THE JOURNAL

CME was founded in 1983 by the publishers E & FN Spon, in conjunction with the founding editor John Bennett at the University of Reading. Originally, one of the principal objectives of the journal was to foster links between industry and academia and address subjects that could 'bridge the boundaries between the traditional professions and craft of the construction industry' (Bennett 1983). In the UK, recently launched CM programmes were not supported by established theories or research methodologies and, at the same time, practitioners saw the journal as a forum for accelerating positive changes in the industry. Under Bennett's editorship the journal doubled in size, from three yearly issues in 1983 to six issues in 1991. In that period two journals merged into CME: *Construction Papers* (CIOB) and the *International Journal of Construction Management and Technology* in 1983 and 1987 respectively. Ranko Bon and Will Hughes took over the editorship of the journal in 1992, and Will Hughes became sole editor in 2003. Under his tenure the size of the journal has increased to 10 issues per year. Currently CME focuses on the management and economics of building and civil engineering as well as that of built facilities. For the purposes of this study and to facilitate the analysis of historical trends, the statistical data are organized into six four-year periods of observation that span 24 years, from 1983 to 2006. In the observed period, 1173 papers (including notes and comments) were published in the journal, with 2412 authorships, as shown in Table 1.

Table 1: Size and authorship of the journal over 1983–2006 period

	83–86	**87–90**	**91–94**	**95–98**	**99–2002**	**03–06**	**83–2006**
Number of issues	12	16	24	24	30	40	146
Number of papers	66	102	155	200	296	354	1173
Number of authors	101	175	286	391	654	805	2412
Authors per paper	1.53	1.72	1.85	1.96	2.21	2.27	2.06
Percentage of UK authors	0.55	0.39	0.49	0.47	0.30	0.29	0.36
Percentage of Commonwealth authors	0.16	0.23	0.25	0.29	0.44	0.37	0.34
Percentage of authors from the rest of the world	0.29	0.38	0.26	0.24	0.26	0.34	0.29

The number of papers published in CM increased by more than 500%, from 66 in the first observed period (1983–86) to 354 in the last period (2003–06). Such growth is also reflected in the number of authors (note that some authors published more than one paper in a given year) from 101 in the first period to 805 in the last period. The ratio of 'authors per paper' has also increased, from 1.53 to 2.27 over the entire observed period. This trend is probably driven more by the 'publish or perish' paradigm than by increased collaboration. As expected, the data show a decreasing UK authorship over the years, considering the tremendous growth of contributors and papers in the last 10 years of publication. The slack has been taken up by authors from Commonwealth countries, particularly from Hong Kong (15% of the total), Australia (10%) and Singapore (6%). In the category 'rest of the world' (29%), North American authors are the largest group (more than 40% of the authorship in this category). The breakdown of authorship by geographic area shows that CM draws 70% of contributors from countries that share similar social, institutional and educational systems (UK and Commonwealth). The relatively small share of contributors (17%) from countries other than the previous group and North America suggests that, even considering language barriers, CM as a field of inquiry and practice does not attract the same interest as in the Anglo-Saxon world.

GATHERING OF JOURNAL DATA AND CLASSIFICATION CRITERIA

The content of this paper builds upon a database that records the title of each paper, abstract, key words, author/s, their affiliation and country of origin. Data were drawn from the ARCOM database which is available on line. As stated above, one of the goals of the research was to classify and group the content of the papers according to subjects. To this purpose the following and previously developed classification framework (Pietroforte and Stefani 2004) was used:

1. Management of the firm
2. Construction planning and control
3. Time scheduling
4. Site and equipment management
5. Construction methods and materials
6. Human resources
7. Project management
8. Cost estimating and models
9. Project delivery systems
10. Contractual issues
11. Industry issues
12. Research and innovation issues

Successively the content of the abstracts and related keywords were classified according to a set of topics that describe each of the considered subjects. In this regard more than 100 topics were addressed. The order of the above-listed subjects reflects three broad ‘perspectives’ according to which the content was interpreted: the first six subjects focus on the operations and business of a construction-related firm, the following four subjects focus on the project planning, organizing and control by a client (or his/her representative), while the last two subjects focus on issues related to the construction industry at large including those related to construction economics. The CM discipline builds upon an array of knowledge domains from social sciences and engineering science, among others. Since its establishment by practitioners, there have been efforts by the academic community to systematize its knowledge, traditionally based on experience. These efforts encompass exploratory studies of construction phenomena, analytical constructs, modification/application of theories from other disciplines and applications of techniques (often drawn from operations research) to solving soft and hard construction process problems. The interdisciplinary nature of CM is reflected in Table 2 which shows the type of disciplinary sources or academic institutions of the 2412 considered authors. It should be noted that there have been changes in the title of schools and departments. The internationalization of the journal, in addition, suggests that different terminologies are used to describe construction-related programmes (e.g. industrial engineering) outside the Anglo-Saxon world. The resulting classification, consequently, aims at a loose identification of contributing disciplinary sources such as engineering, architecture, surveying, management and social sciences rather than presenting an accurate picture of the academic location of the CM field. Over the 1983–2006 period, contributors from engineering (civil, building and industrial engineering) appear to form the largest group (approximately 41%), followed by those from areas such as surveying (approximately 31%). Most of the increase in the group of consulting and construction firms is driven by government research agencies. Over the years CME has not attracted many contributions from practitioners. The sizeable number of contributors (approximately 7%) from institutions not directly affiliated with construction (i.e. economics, social sciences and business) suggests that CM and construction economics are recognized as a distinct field of enquiry by scholars from other established disciplines.

Table 2: Disciplinary origins of contributions

	83–86	87–90	91–94	95–98	99–2002	03–06	83–2006
Consulting, construction firms and government agencies	7	20	17	26	66	86	222

Total	100	174	281	383	646	796	2412

EVOLUTION OF THE JOURNAL CONTENT

As stated earlier, one of the objectives of the study was to assess the content of the journal and its evolution over the years. Table 3 shows the counts of the classified subjects over the examined period.

Table 3: Classification of abstracts by subject (in percentage)

	Subjects	83–86	87–90	91–94	95–98	99–2002	03–06	83–2006	83–94	95–2006
1	Management of the firm	0,09	0,16	0,14	0,08	0,21	0,19	0,16	0,14	0,17
2	Construction planning and control	0,08	0,04	0,06	0,06	0,06	0,03	0,05	0,06	0,05
3	Time scheduling	0,03	0,04	0,02	0,05	0,03	0,03	0,03	0,03	0,03
4	Site and equipment management	0,05	0,04	0,03	0,05	0,05	0,05	0,04	0,03	0,05
5	Construction methods and materials	0,00	0,02	0,02	0,01	0,01	0,03	0,02	0,02	0,02
6	Human resources	0,03	0,11	0,07	0,07	0,05	0,08	0,07	0,07	0,07
7	Project management	0,11	0,07	0,11	0,06	0,09	0,09	0,09	0,10	0,08
8	Cost estimating and models	0,24	0,12	0,13	0,12	0,06	0,07	0,10	0,15	0,08
9	Project delivery systems	0,08	0,07	0,06	0,09	0,08	0,08	0,08	0,07	0,08
10	Contractual issues	0,05	0,05	0,05	0,07	0,04	0,03	0,05	0,05	0,04
11	Industry issues	0,23	0,23	0,23	0,23	0,28	0,26	0,25	0,23	0,26
12	Research and innovation	0,03	0,07	0,09	0,14	0,04	0,06	0,07	0,07	0,07

The frequency of subjects varies from a minimum of 2% (construction methods and materials) to a maximum of 25% (industry issues). The large size of this last subject is driven by topics such as construction economics, international construction and housing issues. More than 30% of the subjects pertain to a body of knowledge that is typically deployed with professional advisory services to clients (cost estimating, project management and project delivery systems) that are typical of professionally oriented firms. On the other hand, a relatively low number of subjects related to technology (subjects 4 and 5) has been observed. This pattern is not surprising since CME's mission does not strongly embrace technology issues. In the last 12 years, however, there has been an increasing interest in technology-related topics such as site equipment management, logistics and site related environmental issues, as shown by the trend of subject 4. This interest was probably spurred by several UK government reports advocating better productivity in the industry. Although productivity improvements are also achieved with more efficient technologies, nevertheless the number of papers pertaining to this subject (construction methods and materials) has remained relatively low. If the 1983–94 and 1995–2006 periods are compared, no significant changes are observed within the considered subjects, with the exception of cost estimating and models whose counts almost halved. This apparent stability actually hides many changes in the topics that make up each subject, as will be shown later in the paper. Some of these changes are shown in the 'perspective' dimensions or level of analysis that characterizes the published contributions, as shown in Table 4.

Table 4: Classification by perspective of the abstracts (in percentage)

Perspectives	**83–86**	**87–90**	**91–94**	**95–98**	**99–2002**	**03–06**	**83–06**	**83–94**	**95–2006**
Firm	0,27	0,40	0,34	0,31	0,41	0,41	0,37	0,34	0,38
Client	0,47	0,30	0,35	0,34	0,28	0,27	0,31	0,36	0,29
Industry	0,26	0,29	0,32	0,36	0,32	0,32	0,32	0,30	0,33

The overall count is almost equally distributed according to firm, client and industry level of analysis. A closer observation of the 1983–94 and 1995–2006 periods suggests that CME's contributors are moving away from addressing the management of projects (client's perspective) and towards the operations of firms and general issues of the construction industry. Past analysis of another related academic publication, ASCE *Journal of Construction Engineering and Management*, has shown an overwhelming interest in the operations of construction firms (more than 65% of cases) and significantly less emphasis on project or industry level of analysis, 19% and 15% respectively (Pietroforte and Stefani 2004). Most published contributions are by authors from civil engineering schools.

Table 5 shows the count of the topics that make up each subject. Because of space limitation, only topics with at least seven counts are recorded. New topics that appear in the 1995–2006 period are in italics. It should be noted that almost all listed topics show an increasing number of counts. This was expected considering that in 1995–2006 the number of papers increased by more than 250% if compared to that of the 1983–94 period.

Table 5: Classification of abstracts by topic

Topics	**83**	**95**	**83**
	94	**2006**	**2006**
1. Management of the firm			
Bidding activities and strategies	15	27	42
Business planning and strategy	12	24	36
Inter-firm relationships	0	31	31
Corporate programmes, e.g., TQM, JIT	0	17	17
Accounting & financial management	3	12	15
Corporate culture, organization structure	6	6	12
Management of information systems	4	8	12

Topics	**83**	**95**	**83**
	94	**2006**	**2006**
8. Cost estimating and models			
Cost modelling, cost data	9	15	24
Deterministic estimating techniques	8	10	18
Non-deterministic estimating techniques	5	11	16
Cost control, project cash flow	9	7	16
Life cycle costing	6	9	15
Time cost integrated considerations	3	10	13
Quantity surveying	7	3	10

Adoption of innovation	0	8	8
2. Construction planning and control			
Resources planning and allocation	4	9	13
Planning of construction, phasing	8	5	13
Production control systems, criteria	2	10	12
3. Time scheduling			
Non-deterministic time scheduling techniques	2	8	10
Time duration estimate, variability	1	7	8
4. Site and equipment management			
Equipment costing, selection and management	5	12	17
Material and component management, handling	3	6	9
Preservation of historic sites and buildings	2	6	8
Environmental contamination and management	0	7	7
5. Construction methods and materials			
Evaluation of methods and building parts	4	6	10
6. Human resources			
Safety issues and programmes, management	7	24	31
Management characteristics and style	7	14	21
Factors influencing productivity and performance	6	14	20
7. Project management			
Design and value management	5	18	23
Project environment and culture	1	11	12
Project planning and organization	12	11	23
Project quality planning and control	5	9	14
Project risk analysis and management	5	6	11

9. Project delivery systems			
Project delivery systems with private financing	1	20	21
Evaluation of capital investments	7	13	20
Project delivery systems and contracts	5	12	17
Selection and evaluation of contractors	2	12	14
Financial evaluation, failures	1	7	8
10. Contractual issues			
Claims and disputes, negotiation, resolution	7	19	26
Management of contractual clauses	3	10	13
Contractual clauses and risk allocation	5	7	12
11. Industry issues			
Foreign construction issues and practices	21	55	76
Economic studies	19	48	67
Housing issues	6	22	28
Roles and cooperation in the industry	8	16	24
Environmental issues in construction	0	21	21
Women and minorities in construction	1	17	18
Codes, standards and information systems	1	15	16
UK industry structure and performance	5	10	15
Industrial relations, workforce issues	5	8	13
12. Research and innovation			
Research methodologies and needs	5	31	36
Innovation and technology transfer issues	6	15	21
IT-based integration and communication	6	4	10
Construction automation and robotics	3	4	7

The following are the topics with the highest number of counts and growth:

- Bidding activities, business planning and strategies, inter-firm relationships, corporate programmes, accounting and financial management (subject 1)
- Resources allocation and production control systems (subject 2)
- Equipment costing selection and management (subject 4)
- Safety issues, productivity factors and management, characteristics of managers (subject 6)
- Project management and organization, design management, project quality issues (subject 7)
- Cost modelling and data, non-deterministic estimating and time/cost considerations (subject 8)

- Project delivery systems with private financing, e.g., BOT, evaluation of capital investments and contract and project delivery systems (subject 9)
- Claims and disputes resolution, and management of contractual clauses (subject 10)
- Non-UK construction issues, economic studies, housing, roles in the industry, environmental issues, and women and minorities in construction (subject 11)
- Research methodologies and debates, and innovation issues (subject 12)

There are other topics, not shown in Table 5, that did not appear in the 1983–94 years: constructability analysis, environmental management, selection of consultants and management of project cooperation. Without doubt the comparison of the topics addressed in the two observed periods suggests that the content of CME has indeed expanded and evolved. If the subjects encompassing the perspective ‘firm’ are considered, in the 1995–2006 years there has been a growing interest in management theories for corporate strategies and operations, and in techniques such as TQM and JIT, as well as cooperation among the firms involved in construction projects. These new dimensions have expanded the knowledge domain of business management that previously was mostly dominated by bidding activities and strategies. Furthermore the second observed period is characterized by a thrust towards understanding the behaviour and characteristics of human resources within construction-related organizations. The count of subjects with the ‘client’ perspective did not increase as much as those encompassing the perspectives of the ‘firm’ and ‘industry’. This pattern may suggest that the body of knowledge pertaining to project management did not evolve or expand much over the years. Quite the contrary, and particularly in the last observed period, new dimensions emerge with an increasing interest in professional services that enhance the quality of projects and the value of designs submitted to clients. Project management expands the range of its activities to include the consideration of new project delivery systems (particularly public projects with private financing) and the evaluation of related capital investments, beyond the traditional cost advice activities of the first period. At the same time the increasing number of contributions focusing on claims, disputes and their resolution, as well as on the management of contractual clauses in general, underlines the growing legal complexity of modern construction. The third perspective, ‘industry’, of contributions shows the relative largest number of emerging new topics, such as environmental issues, role of women and minorities in construction, and international standards, e.g. ISO. Established fields such as construction economics have continued to expand. The initial emphasis on microeconomic aspects (e.g. cost estimating and bidding) has been complemented by macroeconomics aspects focusing on the economic structure of the construction industry and its interplay with the rest of the economy. The growing number of international authors is reflected in the many studies pertaining to non-UK construction industries and practices. Lastly, the large number of contributions focusing on research methods and relative debate among academicians underlines the need for establishing theories in the CM field. Unfortunately, most of the observed debate is not complemented by studies that reflect practice research. Over the years, in fact, contributions to CME seem not to have developed ‘hand-in-hand with the leading edge of practice’, one of the original intents of the journal (Bennett 1983). Lastly, the paucity of contributions addressing IT applications should be noted. This pattern is puzzling considering the wide adoption of web-based integration and communication tools and 3-D and 4-D modelling in the industry. A possible reason for such a pattern may be the existence of several IT-related academic journals that attract most contributions of this type. Overall the CM and construction economics disciplines, as they have been represented in the journal, have expanded considerably over the years with the addition of new fields of study or sub-disciplines, as shown by the number of topics in Table 5. It is suggested that future CME editorial efforts reflect such a growth and aim at structuring these two disciplines into sub-fields or areas of study according to which future contributions could be organized and published.

CONCLUSIONS

Since its inception in 1983, CME has grown significantly in terms of published papers and contributing authors. This growth has taken place particularly with the single editorship of Will Hughes. In the past four years (2002–06) the number of published issues was more then three times that published in the 1983–86 period, a sign that CM and construction economics have attracted the interest of a wide spectrum of contributors. The progressive growth of CM is also reflected in the launching of several related academic journals around the world. Notwithstanding new competition, CME has been attracting more and more contributions. Over the years the relatively decreasing share of UK authors has been more than compensated for by the explosive growth of authors from Commonwealth countries, particularly in East Asia. This growth is not confined to former UK colonies and territories, but is also reflected in the increasing participation from the rest of the world. The majority of the contributions to CME are from surveying, architecture and engineering academic-related areas. The journal has also attracted a sizeable number of authors from areas not directly related to construction. This wide range of contributing sources suggests that CM and construction economics are recognized as a distinct field of enquiry by members of various disciplines and that, at the same time, CM in particular does not have a single academic locus, as in the case of more established disciplines such as law or medicine. Over the life of CME, contributors have shifted the focus of their scholarly endeavour. The initial emphasis on managing projects has been losing momentum and has been replaced by contributions that are concerned with the operations of firms and matters pertaining to the construction industry at large, both domestically and internationally.

The body of knowledge published in CME has expanded with the addition of new fields of enquiry pertaining to the strategic and operational aspects of firms, and the management of projects (particularly the planning and design phases) and contractual clauses. This growth, however, has not occurred uniformly. The important area of technologies (e.g. construction methods and materials as well as IT applications) has not received enough attention, notwithstanding the fact that technological advances are positively impacting on the performance of highly developed construction industries around the world. In an era of increasing global competition, the impact of technology on improving productivity should not be overlooked.

ACKNOWLEDGEMENTS

The authors wish to thank Dr Will Hughes for providing valuable data for developing this study.

A REVIEW AND CRITIQUE OF CONSTRUCTION MANAGEMENT RESEARCH METHODS

Andrew Dainty[1]

Department of Civil and Building Engineering, Loughborough University, Loughborough, Leicestershire LE11 3TU, UK

As the construction management field has grown and matured over the past 25 years, it would be reasonable to expect that the methodologies employed by researchers will have diversified to reflect the multiple traditions and perspectives from which researchers now draw. An indication of a broadening methodological outlook was reflected in the debate within *Construction Management and Economics* around 10 years ago, in which proponents of both positivist and phenomenological methodologies debated the relative merits of each philosophy and the insights that they provide to social research within the community. This paper examines the extent to which this debate, and the ongoing maturation of the discipline, has resulted in methodological pluralism within the construction management field. A cross-sectional analysis of research published within *Construction Management and Economics* in Volume 24 (2006) reveals that the community's research is still overwhelmingly positivist in its orientation, with a resultant reliance on quantitative methods. Of the small number of studies that employed interpretative methods, the majority relied exclusively on open-ended interviewing. The findings of this analysis have fundamental implications for the efficacy and validity of research which seeks to understand the social worlds of those who work in the industry. It is argued that the apparent lack of methodological diversity and adventure in interpretative research design renders the community unable to provide a rich and nuanced understanding of what it means to 'do' construction management. The findings will, however, be reassuring to those who see interpretivism as unscientific and positivism as an insurance against 'bad science'.

Keywords: interview, methodology, research methods, sociology.

INTRODUCTION

As a research discipline which lies somewhere between the natural and social sciences, for many years construction management has been subject to the ascendancy of positivism and quantitative method (Fellows and Liu 2003). In the mid-1990s *Construction Management and Economics* hosted a philosophical debate on the role of theory in construction management and the research paradigm of construction management researchers. This debate was initiated by two papers in particular (Seymour and Rooke 1995; and Seymour *et al.* 1997), which questioned the dominance of rationalist research paradigms and the value of theory within construction management research. They invoked a vigorous and somewhat polarized debate around the relative merits of different research paradigms. In their papers, Seymour and Rooke (1995) and Seymour *et al.* (1997) implicitly questioned the dominance of the rationalist position which seemingly underpinned most research within the community. They suggested that this tacitly endorsed the very attitudes in

[1] a.r.j.dainty@lboro.ac.uk

need of change in the industry, and suggested that the culture of research must change if researchers were to have an influence on the industry. In responding to Betts and Lansley's (1993) review of the first 10 years of the journal, Seymour *et al.* (1997) further questioned the dominance of the scientific theorizing associated with realist ontological and epistemological positions given that the 'object' of most construction management research is people. This suggested that the construction management discipline underestimated the interpretive process.

In the debate which ensued, Seymour and Rooke and Seymour *et al.* were subjected to an intellectual 'broadside' from established researchers within the construction management community. Seymour *et al.* (1997) were accused of being 'anti-scientific' and of propagating an approach which has yet to yield productive output, theories or progress (Runeson 1997). Further, they were accused of promoting an approach more akin to consultancy than research, and of advocating methods which themselves have been widely criticized within the sociological literature (Harriss 1998). Seymour and Rooke (1995) were accused of setting out battlelines in the way that they dichotomized rationalist and interpretative paradigms to the detriment of research standards (Raftery *et al.* 1997). Seymour and colleagues defended their position by counterclaiming that Raftery *et al.* (1997) themselves undermined standards by failing to recognize that different methods suit different purposes and that their position was symptomatic of the widespread confusion over terms such as 'method', 'methodology' and 'paradigm' (Rooke *et al.* 1997). They also questioned Runeson's definition of 'science', defending the rigour of the methods associated with the interpretive paradigm and their value in establishing the meaning ascribed by the social actors being studied (Seymour *et al.* 1998). Various other authors weighed into the debate (e.g. Edum Fotwe *et al.* 1997), with some questioning its value given the apparent focus on research methods as opposed to methodology (Root *et al.* 1997). At the time, some researchers went to greater efforts to explain the philosophical position underlying their research.[1] And then the debate dissipated.

More than a decade later, a series of questions emerge in terms of the legacy of this debate in terms of the impact it has had on construction management research. For example, have alternative research paradigms been embraced, or did the construction management community merely revert to its traditional adherence to positivism and quantitative methods? Furthermore, has there been a move towards mixing paradigms and methods, or have the rival camps within the construction management community remained entrenched and dichotomized within their own epistemological communities? This paper aims to attempt to provide some answers to these questions, *not* in an attempt to reignite the polarized debates around the relative merits of different methodologies and research paradigms, but to establish whether the debate has had a lasting legacy on the way in which the construction management community now 'does research'. It examines the methods utilized by researchers in the most recent complete volume of *Construction Management and Economics* as an indication of the extent to which methodological pluralism has been embraced. In addition, it examines the types of interpretative research methods applied by construction management researchers and questions. Thus, the results reveal both how the construction management research community has responded to the philosophical questions asked of it in the mid-1990s, and the diversity of research approaches that this has induced. The ensuing discussion speculates as to the likelihood of the insights gained through these research approaches informing the development and evolution of the industry that it serves.

RESEARCH STRATEGY AND DESIGN

As a precursor to investigating the methods adopted by construction management researchers, it is necessary to review briefly the decisions which underlie research methodology, strategy and design. Such an understanding enables the appropriateness of decisions as to the most appropriate method to be understood and evaluated in relation to the production of knowledge. Clearly, research methodology in social enquiry refers to far more than the methods adopted in a particular study and encompasses the rationale and the philosophical assumptions that underlie a particular study. These, in turn, influence the actual research methods that are used to investigate a problem and to collect, analyse and interpret data. In other words, research methods cannot be viewed in isolation from the ontological and epistemological position adopted by the researcher.

Objectivist ontology sees social phenomena and their meanings as existing independently of social actions, whereas constructivist ontology infers that social phenomena are produced through social interaction and are therefore in a constant state of revision (Bryman and Bell 2003: 19–20). Epistemology refers to what should be regarded as acceptable knowledge in a discipline (*ibid*.: 13). Epistemological perspectives are bounded by the positivist view that the methods of the natural sciences should be applied to the study of social phenomena, and the alternative orthodoxy of interpretivism which sees a difference between the objects of natural science and people in that phenomena have different subjective meanings to the actors studied. Understanding the influence that competing paradigms have on the way in which research is carried out is fundamental to understanding the contribution that it makes to knowledge. Taking Kuhn’s (1970) definition of a paradigm as a cluster of beliefs and dictates of how research should be done, different research paradigms result in the generation of different kinds of knowledge about the industry and its organizations. The choice of which paradigm to adopt fundamentally affects the ways in which data are collected and analysed.

In broad terms, the term ‘research design’ refers to the process of situating the researcher in the empirical world and connecting research questions to data (Denzin and Lincoln 1994). In other words, it describes the ways which the data will be collected and analysed in order to answer the research questions posed, and so provides a framework for undertaking the research (Bryman and Bell 2003: 32). Making decisions about research design is fundamental to both the philosophy underpinning the research and the contributions that the research is likely to make. For example, qualitative research stresses ecological validity, the applicability of social research findings to those that exist within the social situation studied. Choosing a reductionist approach to examining social phenomena (such as a questionnaire survey) is likely to distance the enquiry from the social realities of the informant, thereby undermining its ecological validity. Thus, methods are inevitably intertwined with research strategy.

In this paper a distinction is drawn between ‘quantitative’ and ‘qualitative’ research. While this distinction is considered by some as unhelpful (see for example Layder 1993), it nevertheless provides a useful framework for categorizing the methods used by researchers. Indeed, it can be argued that quantitative and qualitative research are rooted in particular ontological and epistemological foundations (i.e. objectivism and constructivism, and positivism and interpretivism respectively). Accepting this association between research methods and research paradigms enables philosophical differences in the role that theory plays in research to be viewed through the lens of the methods employed by researchers. Thus, in this research, the methods employed are used as a proxy for the paradigm adopted. It is accepted that this represents an oversimplification of reality. For example, it is plausible that qualitative methods can be employed for theory testing as well as theory generation. However, as will be discussed later in this paper, this is the case in the vast majority of construction management research projects.

QUALITATIVE RESEARCH METHODS

This paper is primarily concerned with the extent of the use of qualitative research methods, which tend to be those associated with the interpretive research paradigm. Qualitative research involves an in-depth understanding of human behaviour and the reasons that govern human behaviour, and so in contrast to quantitative approaches, seeks to establish reasons behind various aspects of behaviour (Wikipedia 2007). There is not room within this paper for an in-depth treatise on the multiplicity of methods that fall under the broad heading of qualitative research (see Denzin and Lincoln 2000; Cassell and Symon 2004; and Silverman 2004, 2005 for this). Moreover, it is important to stress that qualitative research methods is a complex, changing and contested field (Denzin and Lincoln 2000) which is characterized by its diversity (Punch 2005: 134). This is perhaps unsurprising given the inherently subjective nature of qualitative data analysis, whereby the researcher continually shuttles between data analysis, reduction, display and theory generation. Some writers (e.g. Silverman 2003) are overtly critical of attempts to classify qualitative research methods into generic types. This becomes particularly problematic when the ambiguity between theory and research is considered, which is a hallmark of the inductive research paradigm, and the centrality of the subjective interpretation and situational embeddedness of the researcher within qualitative enquiry. However, despite these problems of classification, it is possible to categorize qualitative research methods in broad terms, while accepting that the application of these methods and the interpretation of the results will differ from researcher to researcher.

Although there is no definitive taxonomy of qualitative research methods, a broad classification can be gleaned by examining the classification of methods adopted by leading texts in this area (e.g. Denzin and Lincoln 2000; Bryman and Bell 2003; Cassell and Symon 2004; and Silverman 2005). A brief description of the primary methods used in qualitative research is provided below based on a synthesis of these sources. This broad classification is used to evaluate the methods adopted by researchers publishing in *Construction Management and Economics* later in this article.

Observation and ethnography

Observation can be in two main forms, participant and non-participant. Participant observation is often associated with ethnography, although ethnography refers to both the written output of the research as well as the research and the method. Both approaches involve entering the context of the research as a participant with data usually taking the form of field notes. It often requires a sustained period of intensive work because the researcher needs to become accepted as a natural part of the culture being studied in order to ensure that the observations are of the natural phenomenon. Non-participant observation differs in that the observer attempts to unobtrusively observe the phenomena under investigation. This more detached perspective tends to be more time bounded. Both forms involve profound ethical considerations.

Discourse and conversation

Discourse and conversation analysis are both concerned with the examination of language. Conversation analysis comprises the in-depth examination of talk as it occurs (usually through transcribed discussion) through which the structures of language can be uncovered. Discourse analysis can be applied to any form of text (i.e. there is not an emphasis on naturally occurring talk). The emphasis is on establishing the way in which the social world is constructed through discourse – what is written, said (or not said) – and how this impacts on others' perceptions and experienced realities.

Document and textual analysis

This refers to the analysis of any kind of textual data from personal documents to internet resources. The common feature is that these are secondary sources of information that have not been produced for the purposes of the research study.

Visual data

A relatively recent addition to what are considered qualitative methods is the analysis of visual data. These can include photographs, video, pictures (e.g. cartoons) and any other visual media which convey information on a social situation or setting.

Interviews

Qualitative interviews can either be unstructured or semi-structured. Interviewing involves direct interaction between the researcher and a respondent or group, but whereas semi-structured interviews may follow a framework of questions, unstructured interviews are left to develop naturally around the topic of discussion. In both cases the interviewer is not constrained by a rigid instrument and is free to move the conversation in different directions as relevant issues emerge. A variation on individual workshops is focus groups where the emphasis is on engaging several informants in the joint construction of meaning.

Case studies

Although often referred to as a method, there is no single way to conduct case study research and it will often comprise a number of mutually supportive methods and research designs, some of which may be quantitative. In this study the individual methods used within the case have been categorized within the analysis.

METHOD

In order to examine the methodological positions and research methods adopted by construction management researchers, an analysis was carried out of every paper published in *Construction Management and Economics* in Volume 24, 2006. Each paper was scrutinized for statements as to the methodological position of the author(s) and the methods employed. Where this was not unambiguously stated within a defined section of the paper, efforts were made to identify the methods adopted from the narrative description of the research. In some cases no discernible empirical research methods were adopted as the paper was a review-type contribution. In other cases papers drew upon a multimethodological or multi-paradigm research design. These papers were defined as 'review' and/or 'mixed methods' respectively. Thus, four broad classifications were used for summarizing the methodologies adopted within the papers as follows:

1. *quantitative* – unambiguously adopting quantitative methods rooted in a positivist research paradigm;
2. *qualitative* – unambiguously adopting qualitative methods rooted in an interpretative research paradigm;
3. *mixed methods* – comprising a combination of both inductive and deductive research methods;
4. *review* – not utilizing empirical research methods.

For those papers which reported research which adopted a qualitative (2) or mixed method (3) approach, a further sub-classification step was undertaken to categorize the methods used. These categories were established inductively and were not based on an *a priori* classification of research methods. In this respect, the interpretation of the methods adopted by the papers' studies is itself interpretative. This was necessary as some authors did not unambiguously state their adopted methods. The qualitative methods adopted by the authors can be summarized thus:

1. interviews (semi-structured and unstructured);
2. focus groups and group interviews;
3. observation (non participatory and/or participatory including ethnography);
4. document or other textual analysis;
5. visual data analysis.

It is important to stress that there are several significant limitations of the approach adopted. First, the papers published within *Construction Management and Economics* may not be reflective of the entire construction management research community. A search of papers published in other journals may have revealed that they attract papers from a different constituency of the research community which adopt different research methods. Secondly, this study represents an analysis of only those papers published and not *submitted* to the journal. As such, the analysis may be more representative of the biases of referees rather than being necessarily representative of the methods actually adopted by construction management researchers. A third limitation concerns the nature of the methodological description contained within the papers themselves. This is highly variable and renders any such analysis somewhat tenuous. In addition, it is possible within some of the projects that other methods were employed which have not been unambiguously stated within the papers. These aspects may not have been published or may have been published elsewhere for legitimate reasons (such as word restrictions placed on articles within the journal). A fourth issue concerns the reliability of drawing general conclusions based on a single year's worth of papers. It is possible that papers published in this year were anomalous to the general trends the kind of papers published within the journal. A final issue is that not all of the papers published within the journal can be described as 'social research'. For example, some papers dealt with aspects of construction law or finance, which have only loose connections to social phenomena, for which the utilization of qualitative methods would have been inappropriate. Despite these weaknesses, however, the journal is considered by many construction management researchers to be one of the leading refereed publications in its field. This is supported by the very high levels of copy flow and the high rejection rate (see Taylor and Francis 2007). Furthermore, it is reasonable to assume that, given that reviewers of papers are drawn from the construction management research community, that any bias towards methodological approaches would balance itself out over time. The year selected for analysis, 2006 was the most recent year for which a full year's worth of papers was available. Furthermore, the journal switched to a 12-issue format in 2006 which enables more papers to be considered in the analysis. Thus, while this paper makes no claims as to the statistical reliability of the findings presented, and draws upon a qualitative analysis of the narrative description of the methods employed within the papers, it does enable a simplified cross-sectional view of the dominant position of the research community.

RESULTS

The results of the analysis are presented in Tables 1 and 2. Table 1 presents an overview of the methods used within the research reported in the papers reviewed. These data represent the number of papers utilizing the methods embodied by the broad classifications listed above. This shows that of 107 papers and notes published in Volume 24 of the journal, 76 used quantitative methods. Only nine used qualitative methods exclusively. In addition, a further 12 papers used a mixed methods approach combining qualitative and quantitative methods. It should be noted that in a few of the studies which have been classified as utilizing exclusively quantitative approaches, a brief mention of exploratory interviews was made, although none of these data was reported in the data. Although it could be argued that the qualitative findings may have shaped the resulting enquiry and quantitatively derived results, the fact that they didn't warrant reporting in the papers provides justification for excluding them from the 'mixed methods' classification.

Table 1: Broad classification of research methods reported in all papers (excluding letters and book reviews) in Vol. 24 of *Construction Management and Economics* (n = 107)

	Qualitative methods	Quantitative methods	Mixed methods	Review/other papers
No. of papers	9	76	12	10
(% in parenthesis)	(8.4)	(71.0)	(11.2)	(9.4)

Table 2 presents a breakdown of the types of qualitative methods employed by those employing only qualitative methods and those adopting a mixed methods approach. In this table, papers have been classified under each category if the particular method has been utilized and the results reported in the paper. Thus, this table reflects the *number of times that a method was applied* across the sample of papers. Given that several studies employed a number of methods and datasets, this number is greater than the number of papers identified in Table 1. This table reveals that 16 of the 105 papers published in Volume 24 of the journal used individual open-ended interviews. This represents more than three-quarters of the studies employing qualitative methods. Three studies used focus groups, workshops and/or group interviews, two used forms of observation and three analysed documentary data (mainly as part of case study research). Only one project reported analysing visual data.

Table 2: Classification of research methods reported in papers using qualitative research methods in Vol. 24 of *Construction Management and Economics*[2]

	Interviews	Focus groups, workshops and group interviews	Observation	Document or textual analysis	Visual data
No. of papers	16	3	2	3	1

DISCUSSION

Clearly, the construction management research community has grown and developed since the methodological debates of the mid-1990s. This is demonstrated by the growth in the number of papers published in the discipline's leading journals. As academic departments and facilities have expanded and the numbers of doctoral candidates undertaking construction management research have increased, it could be reasonably expected that their methodological positions and the methods adopted may have broadened and diversified also. However, if the contents of the volume of *Construction Management and Economics* reviewed here are reflective of the community at large, then this is manifestly not the case. The findings raise fundamental questions, both in relation to the narrow ontological and epistemological standpoints of the research community, and in relation to the uniformity of methods that interpretive researchers employ.

Questions of social ontology are concerned with whether social entities are objective realities or social constructions built up from the actions and perspectives of social actors (Bryman and Bell 2003: 19). It would seem on the basis of this analysis that the majority of construction management researchers have retained an objectified view of reality. While it is by no means certain that the predominance of quantitative methods revealed in this paper is inexorably linked to positivist research philosophies,[3] it is highly likely that this reflects an ongoing adherence to natural science methodologies and reductionist approaches to social enquiry within the community. Whether this should be seen as a concern will depend upon the individual standpoint of the reader, but the construction management community's apparent reluctance to embrace methodological pluralism has undoubted implications for the contribution it makes to both research scholarship *and* practice given that much construction management research is based on the co-production of knowledge between researchers and practitioners. It would seem that the research community has continued to adopt a rationalist paradigm in seeking to theorize on construction management as a discipline, with a resultant emphasis on causality over meaning (cf. Seymour and Rooke 1995; Seymour *et al.* 1997). It could be argued that the research community reflects, in microcosm, the industry's wider adherence to instrumentalist and rational solutions to complex managerial problems and situations (see Dainty *et al.* 2007).

A second issue emerging from this analysis concerns the apparent reliance of qualitative construction management researchers on open-ended interviewing. As was discussed above, in contrast with quantitative research design, which remains relatively methodologically unidimensional, contemporary qualitative research is characterized by its diversity (Punch 2005: 134). However, in the volume of *Construction Management and Economics* reviewed, virtually all of the studies which employed exclusively qualitative methods relied exclusively on semi-structured interviews. Within the social sciences, the apparent over-reliance on interviewing has been attracting criticism from researchers who see it as symptomatic of the 'interview society',[4] and of belying the fact that interviews are themselves methodologically constructed social products and not 'experientially authentic truth' (Gubrium and Holstein 2002). In the past, those critical of interviewing have questioned their efficacy based on practical and pragmatic considerations such as the truthfulness of the informant and the differences between what people say and what they actually do (see Hammersley and Gomm 2005). However, a more radical critique of interviews as a research method has recently emerged in which the social construction of what is said, and the fact that they reflect the particular context within which they take place, has been seen as limiting their methodological validity. Such a critique sees the interview informant as being more focused on self-presentation and the persuasion of others, rather than on presenting facts about themselves or the world in which they exist (*ibid*.). Regardless of whether such a radical perspective on the efficacy of interviews is fully accepted, the acknowledgement that they are in any way flawed reinforces the need for data from different sources to triangulate the implications and outcomes that they provide.

An emergent finding warranting further discussion concerns the lack of reflexivity within the papers reviewed. As was alluded to above, there is a tradition of reflexivity in qualitative enquiry where researchers openly question the effectiveness of their research methods on the robustness of their results and debate the influence and effect that their enquiry has had on the phenomena that they have sought to observe. Being reflexive requires a willingness to probe well beyond straightforward interpretation of the data to explore how personal research bias affects the research process itself (Woolgar 1988). Despite this, however, there is an absence of any critical reflection in many of the papers reviewed which adopted qualitative methods. This may reflect that dominant rationalist paradigm of the construction management research community, or even a concern on the part of interpretative researchers that such a reflection would effectively equate to admission of 'fault' in their research designs. However, an apparent reluctance to engage in reflexivity arguably has a detrimental effect on the methodological evolution of the discipline and the development of its theoretical base.

CONCLUSIONS

More than a decade on since the methodological debate invoked by Seymour and colleagues, this paper has revealed that the construction management field appears to have remained firmly rooted within the positivist tradition. It has shown both an entrenched adherence to positivist methods within the community, and a significant reliance on open-ended interviews by those adopting qualitative methods. Clearly, no claims can be made as to the broader significance of these findings as they do not provide evidence of methodological trends, but they do provide limited evidence of an apparent reluctance to embrace paradigmatic change within the construction management community. Moreover, they present a view of a community reluctant to adopt the kinds of radical qualitative research methods which could provide richer insights into industry practice. Contemporary critiques on interviewing methods suggest that they are exceptionally poor at revealing anything beyond the immediate interview situation. Indeed, if interviews are considered to be methodologically constructed social products, then this has worrying implications for the efficacy and validity of qualitative construction management research which has sought to understand the social worlds of those who work in the industry.

For some, the conclusions of this paper will be deeply worrying on several levels. The apparent lack of methodological diversity coupled with an apparent lack of adventure in interpretative research design suggests a research community rooted in methodological conservatism and disconnected from the debates going on in many of the fields from which it draws. They will see construction management researchers as needing to adopt a more pluralistic attitude towards the selection of research methods if they are to develop a richer and more nuanced understanding of the sociology of the industry and its organizations. On the other hand, those who see interpretivism as unscientific and positivism as an insurance against 'bad science' will be reassured that the field has not embraced calls for paradigmatic change.

NOTES

1. The present author was writing up his PhD thesis at the time of this debate, and dedicated over 50 pages of his thesis to justifying the ontological and epistemological position adopted in his work!
2. It should be noted that on several occasions the nature of the data collected and the methods employed were ambiguous. Although a reasoned judgement has been made based on the contents of the paper and the nature of the results, the accuracy of these assertions cannot be guaranteed given the lack of detail within the papers.
3. Surprisingly few of the papers reporting on social research actually stated a methodological position within the volume reviewed. The majority of those that do discuss their research design tended to discuss only the methods employed and not the philosophical assumptions that underpinned their research.
4. An obsession on the part of the mass media to uncover the personal realities which underlie the public facades of the interview subject.

TRIGGERS FOR HOUSING DEVELOPMENT

Philippe Thalmann[1]

Ecole Polytechnique Fédérale de Lausanne, EPFL ENAC INTER REME, Station 16, CH-1015 Lausanne, Switzerland

What leads to the development of residential construction projects? If the economic literature is to be believed, developers analyse market opportunities. However, it is difficult to assess those opportunities, for several reasons, e.g. long time horizon for developers who intend to remain owners of the completed dwellings and no coordination between developers. The latter problem concerns particularly developers who intend to sell their project upon completion (market developers). Is housing development really predominantly the result of market analysis? Micro analyses reveal that particular circumstances also play an important role: the availability of a particular piece of land, financing conditions, land regulation, etc. This article is designed to assess the shares of projects that are initiated on the basis of market analysis as opposed to other trigger factors. If that share is small, it is unlikely that house building can be explained or predicted with standard economic models of supply and demand. It also means that macroeconomic housing policy (lowering interest rates, subsidies designed to increase profitability, even rent deregulation) will not be very effective. A unique database was created by surveying 2257 developers who built multi-unit residential buildings in the 1990s in Switzerland.

Keywords: housing development, housing policy, property development, Switzerland.

INTRODUCTION

The importance of understanding the drivers of housing supply is amply documented, e.g. for the UK by Ball (1996a and 1996b). What leads to the development of residential construction projects? If mainstream economic literature is to be believed, developers analyse market opportunities and maximize their profit intertemporally. When they see sufficient demand for new developments and expect to earn an adequate return on their investment, they purchase land and the other resources needed to make dwellings, produce them and put them on the market. In other words, supply responds to demand. Only the unavoidable delays between the observation of adequate market conditions and delivery of new dwellings can cause disequilibria on the housing market, which vanish as soon as developers have a chance to adjust their supply (e.g. Kenny 2003). For surveys of the housing supply literature, see DiPasquale (1999).

The surge of behavioural economics is renewing the interest in economic decision making. Scanlon and Whitehead (2006: 25) recently did so for private landlords in the UK and concluded that 'individual private landlords do generally respond to economic stimuli in rational ways'. However, they found ample evidence of short-sightedness, asymmetry in responses to changing opportunity costs, insufficient consideration of opportunity costs, and liquidity constraints. De Bruin and Flint-Hartle (2003) tested whether a bounded-rationality model better describes the investment choices of

[1] philippe.thalmann@epfl.ch

individual landlords in New Zealand. They found that most had bought property for the capital gains promised, but they had done so at a time when inflation was clearly under control, which suggests backward-looking behaviour. They also find evidence of bounded rationality in the fact that investors' portfolios are very little diversified.

Indeed, the simple profit-maximizing model of housing supply can be challenged on several grounds. It is difficult for developers to be aware of what their competitors are preparing, so they might answer to the same perceived demand with excess supply. On the other hand, not all developers need to make their profit from the immediate sale of their product. Many have the option and choose to remain owners of the new buildings and rent them, so that the return on the investment can be earned gradually over time. This complicates considerably the developer's calculation of profit opportunities. It also makes it very difficult for outside observers to test whether developers are really performing a thorough project analysis before launching a development. Expectations ought to play a much more important role than current market conditions, and expectations are notoriously hard to observe. Scanlon and Whitehead (2006) observed that fact when testing the rationality of private landlords in the UK. They noted that the same market signal may just as well justify an increase in housing investment as a decrease. Consider an increase in property prices. It implies smaller rental return and greater risk. It can even be taken as a signal of future price corrections (mean reversion). On the other hand, property price increases signal rising housing demand. It takes a thorough analysis of price changes to predict their consequences for future profitability and even experts disagree on them.

Experts even disagree on how the profitability of housing investment ought to be assessed. Some ignore its capital gains component (Skifter Andersen 1998). Some consider that landlords are irrational if they do not leverage their property to take advantage of low mortgage interest rates (Ball 2004) while others might consider that the risks and unattractive investment alternatives for the freed equity justify full ownership for many landlords. Even decreasing stock market prices need not command a portfolio reallocation in favour of rental property, as many financial advisers recommend targeting fixed portfolio shares, which implies buying more shares when stock markets slump.

In the face of difficult project analysis, many developers might use shortcuts and place their faith in the long life expectancy of their products, which can generate adequate returns when given sufficient time. They might launch developments when local circumstances are favourable (e.g. a neighbour develops her property) or some other fortuitous event occurs (e.g. the developer is proposed a plot of land). On the other hand, partial negative signals such as rising land or construction prices, a slack in economic growth or a spike in vacancies may discourage them from developments that thorough analysis might still show to be profitable.

This article is designed to assess the shares of projects that are initiated on the basis of market analysis as opposed to other trigger factors. If that share is small, it is unlikely that house building can be explained or predicted with standard economic models of supply and demand. It also means that macroeconomic housing policy (lowering interest rates, subsidies designed to increase profitability, even rent deregulation) will not be very effective.

It seems that the only way to learn about the triggers of housing developments, in particular the importance of market conditions and housing needs, is to ask developers. This is what this paper does. It draws from a survey that is part of a wider research project designed for understanding why housing construction had declined so much in the second half of the 1990s in Switzerland in spite of apparently quite favourable conditions. The results of that project were published as Schüssler and Thalmann (2005).

CONTEXT OF THIS RESEARCH

In Switzerland, rental housing accounts for about one-half of all new developments and it still houses about two-thirds of all households.[1] Moreover, it houses the households that have least housing choices and tend to suffer most from housing shortage. The Swiss case study is also interesting for the country's long history of housing shortage. Observers consider that the market is balanced when the national vacancy rate reaches a mere 1.5%, a rate that was only exceeded in four of the last 30 years. The question of why there is not more housing development and what triggers development is clearly warranted on such a market.

The Swiss market is also characterized by its high fragmentation: 57% of all rental dwellings belong to private individuals (2000 Census).[2] The rest belongs to a myriad of small pension funds, small cooperatives, local authorities and very few large institutional investors. There are over 4000 construction firms in main construction (not counting painters, etc.), so that the average construction volume per firm is less than a million euros and the average number of personnel is around 20. Finally, over 40% of all dwellings are developed by individuals and a third by the myriad construction firms and real estate companies. Thus, developers are just as fragmented as the rest of the market.

We shall see that it is necessary to distinguish between market developers, who build with a view to selling the completed building to final investors (who include users in condominium ownership), and final investors who build themselves. The difference is that market developers need to anticipate investors' desire to invest. There is an intermediate solution, whereby the market developer develops a project at the request of an investor. This last solution is rather uncommon in Switzerland.

Developers are not registered as such. They are construction firms, real estate companies, architects, and many individuals (Table 1). To find them, we used the systematic record of construction permits compiled by the periodical *Baublatt/Batimag*. The purpose of that publication is to allow small contractors to learn about building projects and offer their services. We restricted our analysis to buildings containing two dwellings or more in order to eliminate all the single-family developers, who are generally the occupants themselves in Switzerland. In addition, we focused on building permits delivered in two specific periods: 1994–96 and 1999–2001. The first was a period of relatively high housing construction and the second was a trough.

Table 1: Shares of different types of developers in population and sample

	All new dwellings	New dwellings in multi-family units	2004 survey
Public sector	1.9	2.7	1.2
Institutional investors	4.7	6.7	6.1
Construction firms and real estate companies	33.8	37.3	27.1
Cooperatives	3.3	4.4	7.3
Private persons	41.7	32.0	39.1
Other developers	14.5	16.8	19.1

Notes: Data from Federal statistical office in first two columns; averages over 1994–96 and 1999–2001. The total of each column is 100%.

We administered in the summer of 2004 a survey to one-sixth of all 8695 developers who had obtained exactly one building permit for a building with at least two dwellings between 1994 and 1996 or between 1999 and 2001 ('one-shot developers') and to all 808 developers who had realized more than one project in that period ('repeat developers'). That makes 2257 addressees in a population of 9503. The survey had about 60 questions designed to identify the main determinants and triggers of house building and the hurdles and barriers developers face. The results presented here are based on the returns from 316 one-shot builders and 200 repeat builders. They represent 23% of the initial sample or 5.4% of the population. Based on the number of dwellings the respondents declared they had built in the two periods, they also represent about 22% of all dwellings built in multi-family units.

The relatively low rate of return on our survey can be explained by several factors. Many developers no longer existed as an organization or at the old address in 2004, particularly those who had built in the mid-1990s. In addition, addressees who had obtained a building permit for a transformation or renovation were asked not to respond, and that concerns about one-third of all building permits. Nevertheless, our final sample is quite representative of the population of developers (Table 1). Only private persons are somewhat over-represented and construction firms and real estate companies under-represented in our survey.

THE MAIN CATEGORIES OF DEVELOPERS

For understanding development triggers, it is essential to distinguish between short- and long-term oriented developers:

1. Developers who seek to sell the completed dwellings or building with a profit; we shall call them 'market developers'.
2. Developers who build with a view to keeping ownership of the completed building; we shall call them 'investor developers'.
3. Developers who sometimes sell the completed dwellings or building and sometimes keep the completed building; we shall call them 'market/investor developers'.

Table 2 indicates the proportions of each category of developer in the two periods of analysis. The strong increase in strata ownership development accounts for the progression of the share of market developers: in 1999–2001, almost 60% of the projects were built by market developers who sold the flats to individual buyers. Those developers are classified as 'market developers' or 'market/investor developers' depending on whether they also built dwellings that they did not sell.

Table 2: Importance of the categories of developers in 1994–96 and 1999–2001, based on 2004 survey

	Mid-1990s	**End 1990s**
Market developers	22	43
Market/investor developers	30	33
Investor developers	48	24

Notes: Answers of 449 developers. The total of each column is 100%.

Finer distinctions can be made within each category to understand their mode of operation and the triggers that lead them to initiate a housing development. We shall consider in turn market developers and investor developers. The answers of the market/investor developers will be used in both sub-samples.

THE TRIGGERS OF DEVELOPMENT BY MARKET DEVELOPERS

A central distinguishing characteristic among market developers is the frequency with which they launch developments. Those who build repeatedly are assuredly more ‘professional’ than those who build only once in their lifetime.[3] Table 3 shows that there are almost as many market developers who build regularly as market developers who build rarely. In what follows, we shall call the former ‘frequent market developers’ and the latter ‘occasional market developers’.

Table 3: Shares of market developers by frequency of developments, 2004 survey

They develop multi-family buildings …	
… frequently, always for the same investor or group of investors	15
… frequently, for different investors	38
… rarely	35
… never except that unique time	12

Notes: Answers of 323 market or market/investor developers. The total of the column is 100%.

The types of organizations that act as market developers are described in Table 4. It is interesting to note the high proportion of individuals, particularly among the occasional market developers. Nevertheless, construction firms and architects dominate the market, particularly among the frequent market developers. This suggests that market developers often launch a development for the work it provides them, an assumption that was confirmed when we asked them for the main triggers that made them launch a housing development project (Table 5). The somewhat fortuitous opportunity created when someone proposes a plot of land or a construction project comes a close second. Only about one-quarter of the market developers indicated that they launched developments on the basis of their analysis of the market. This is not to say that the other market developers do not analyse the market prior to their developments. It means that very few market developers are actively monitoring the market for business opportunities and therefore likely to respond to housing demand.

Table 4: Types of organizations that act as market developers, 2004 survey

	Occasional market developers	**Frequent market developers**
Individuals	30.4	14.0
Unshared inheritances	6.3	–
General contractors	14.3	36.7
Other construction firms	10.7	7.3
Architects	20.5	25.3
Real estate firms	7.1	10.7
Cooperatives	4.5	3.3
Others	6.2	2.7

Notes: Answers of 262 market or market/investor developers. The total of each column is 100%.

Table 5: Triggers and conditions for launching a housing development project, 2004 survey

Motives that usually lead market developers to launch a housing development project	**Occasional market developers**	**Frequent market developers**
The need to occupy their business capacities	44	70
A piece of land or construction project is proposed	46	62
Their own market analysis	14	30
The demand of a final investor	5	23
Other reasons	25	9

Notes: Answers of 275 market or market/investor developers. Several answers allowed. Column percentages.

We asked market developers how they estimated the profitability of a development project. Their answers are represented in Table 6. Three-quarters indicated that they systematically analyse the project and the local market. That leaves one-quarter who do not, particularly among occasional market developers. Half of the market developers also indicated that they refer to the recent evolution of property prices, which hints at static expectations. Very few refer to the evolution of interest rates and rents, which are important determinants of property prices in theory. Even fewer refer to outside experts.

Table 6: Market developers' references for estimating the profitability of a project, based on 2004 survey

	Occasional market developers	**Frequent market developers**
A systematic project and local market analysis	65	81
The recent evolution of property prices	44	51
The recent evolutions of interest rates	16	19
Consulting experts	16	6
The recent evolution of rents	5	18
Other references	8	10

Notes: Answers of 272 market or market/investor developers. Several answers allowed. Column percentages.

This analysis has shown that market development is dominated by construction and construction-related firms. As a consequence, the main motive for launching developments is the need to keep business resources occupied. Very few projects are launched by market developers on the basis of a market analysis. This does not mean that market conditions play no role. Indeed, even developers who seek the revenue more than the profit perform a systematic project and market analysis and generally require that a minimum share of the project be pre-sold and the financing almost fully assured before they launch a development project. Still, the pressure to generate work, particularly when investors may not hand out too much of it at a time of low construction, might induce construction firms to shortcut some of the market analysis. At the end of the 1990s, there was clearly too little construction by investors in the face of housing demand in Switzerland, as evidenced by a very low vacancy rate. Market developers increasingly became the main suppliers of new housing, in the form of strata ownership. They thus helped strata ownership's share in the housing tenure boom from a very low level (from 4.4% in 1990 to 7.9% in 2000).

Our survey also showed that many market developers are individuals who may develop just one project in their lifetime, typically in response to a fortuitous opportunity, such as the inheritance of a piece of land. It is difficult to assess the importance of that form of housing supply, but since occasional market developers represent almost half of all market developers and since the opportunity of a piece of land or construction project proposed was cited as a trigger by about half of all market developers, it is not implausible that about half of all market developments have that fortuitous character. That creates a large stochastic component in housing supply.

In a nutshell, about half of the market development projects appear fortuitous and only half are based on market analysis. In addition, that market analysis is often tainted by the market developers' wish or need to occupy production capacities. Nevertheless, market developers slowed down the decline in housing construction in the second half of the 1990s, when investors appeared to quit that activity. Let us now turn to the developers who build a property to hold it themselves and try to understand what drives their development decisions.

THE TRIGGERS OF DEVELOPMENT BY INVESTOR DEVELOPERS

All investor developers develop projects to let the apartments, but they can do so with quite different objectives:

1. Developers who seek a profitable investment; we shall call them 'profit driven'.
2. Developers who pursue social goals with their rental dwellings and seek to address housing needs; we shall call them 'social'.
3. Developers who are foremost interested in the work provided by development to occupy their idle capacities; we shall refer to them as 'revenue driven'.

It is quite likely that many in the latter category would have preferred to sell the building like market developers but could not find a buyer on acceptable conditions. The survey shows that all of them are also market developers (they are all 'market/investor developers' in our terminology, see Table 7). Very few social developers act occasionally as market developers. On the other hand, three-quarters of all pure investor developers are profit driven as well as one-quarter of all market/investor developers. Counting over all investor developers, profit-driven developers are the largest category, about half, followed by a third who are mainly revenue driven and 16% social developers. The small share of the latter is no surprise considering that only some 14% of all rental dwellings belong to non-profit landlords (Kemeny *et al*. 2005).

Table 7: Categories of investor developers, based on 2004 survey

	Pure investor developers	Market/investor developers
Profit driven	73	29
Social	27	6
Revenue driven	0	65

Notes: Answers of 149 pure investor developers and 141 market/investor developers. The total of each column is 100%.

The motives of the types of organizations that develop housing to keep it themselves are closely related to their main motivation (Table 8). Thus, insurance companies and pension funds are always profit driven. Foundations and associations, public bodies and cooperatives almost always declared themselves social. Construction firms and architects nearly always build for the revenue. They constitute the lion's share of revenue-driven developers, just as they do among the market developers. It is interesting to note again the importance of individuals, who are the largest category of profit-driven developers and who are also well represented among the other categories of investor developers. Indeed, 57.4% of all rental dwellings in Switzerland belong to individuals (2000 Census).

Table 8: Types of organizations that act as investor developers, 2004 survey

	Profit driven	Social	Revenue driven
Individuals	55.7	20.8	35.1
Real estate firms	6.7	–	7.4
Cooperatives	2.7	50.0	1.1
Insurance companies	4.7	–	–
Pension funds	12.1	–	–
Foundations	–	4.2	–
Public bodies	–	12.5	–
Construction firms	8.1	2.1	26.6
Architects	8.7	2.1	26.6
Others	1.3	8.3	3.2

Notes: Answers of 149 profit-driven, 48 social and 94 revenue-driven developers. The total of each column is 100%.

What triggers housing developments by investor developers? To answer this question, we shall distinguish the categories of investor developers, even though there are many commonalities (Table 9). An important trigger for all is the arrival of interesting projects: more than a quarter of all investor developers cited this as a trigger. Almost as important is the occurrence of favourable circumstances for developing a piece of land the developer already owned. Thus, we find the same fortuitous character in many housing developments as among the market developers. It is naturally particularly important for investor developers who develop projects only occasionally.

Nevertheless, about one-half of the profit-driven developers actively seek investment projects in multi-family rental housing, comparing them with other investment options or not. Almost 30% of the social developers also seek new projects actively. Almost as many of them indicated that it was their job to build, which can be interpreted as dedication to address recurrent housing needs.

Table 9: Triggers of housing developments by investor developers, 2004 survey

	Profit driven	Social	Revenue driven
Build on a piece of land they own when circumstances are favourable	31	29	19
Invest in multifamily buildings when interesting projects present themselves	29	27	27
Continuously seek multifamily projects but also consider other investments	21	0	4
Invest most of their capital in multifamily buildings and actively seek projects	20	29	11
It is their job to build multifamily buildings	12	20	67
Other triggers	1	7	0

Notes: Answers of 138 profit-driven, 41 social and 73 revenue-driven developers. Several answers were allowed but very few gave more than one. Column percentages.

The survey allows for looking more closely at the motivations of each category of investor developers. Profit-driven developers need to assess the profitability of a project, which is made more difficult by the typically very long holding period. Two-thirds of the profit-driven developers in the survey indicated that they assess a project themselves (Table 10). One-quarter rely on their experience and about as many get outside advice. Almost 90% assess a project themselves when we consider only profit-driven developers who built more than 100 dwellings over the past 10 years. Indeed, it is particularly the occasional profit-driven developers who call upon the advice of third parties, typically their banker, or are content with basic evaluation.

Table 10: How profit-driven developers assess a development project, based on 2004 survey

Overall assessment mode	All profit-driven developers	Large profit-driven developers
Performs a financial analysis	66	89
Relies on his/her experience	27	11
Gets outside advice	23	4
Proceeds otherwise	6	4
Specific objective		
The safety of a long-term asset	55	43
The profitability of the investment	33	54
A steady flow of rental income	12	4

Notes: Answers of 144 profit-driven developers, of whom 28 had built 100 or more dwellings over the last 10 years. Several answers allowed. Column percentages.

When they assess a housing development project, most profit-driven developers seek the safety of a long-term real asset (Table 10). This corresponds to De Bruin and Flint-Hartle's (2003: 275) finding that 'wealth accumulation and long-term capital gain was the most important consideration in the property investment decision' for the New Zealand real-estate investors they surveyed 1999. It is only among the large profit-driven developers in our sample that a majority seek the investment's performance. A steady flow of rental income is particularly interesting for pension funds and pensioners. Landlords may also need it to cover the interest and amortization of their mortgage, which is often very high in Switzerland in international comparison.[4]

In summary, a picture emerges that is quite similar to that of the market developers. Two-thirds of the profit-driven developers are sophisticated in the sense that they analyse more or less thoroughly the potentials of a development project while one-third are happy with plain calculations or experience values, or, in the case of market developers, with the preliminary sale on blueprints of at least half of the dwellings.

De Bruin and Flint-Hartle (2003) saw evidence of investors' bounded rationality in the fact that their portfolios were very little diversified. Indeed, 77% of the landlords they had surveyed indicated that residential rental property was the most important investment in their portfolio; 22% held only property. In our survey, only profit-driven developers who were in the database with several building permits, i.e. relatively large developers, were asked about the composition of their portfolio. For half of them, rental housing property accounted for 60% and more of their portfolios. This is clearly much more than portfolio diversification would warrant. Hoesli (1993) shows that the optimal risk–return performance is obtained in Switzerland with a portfolio that includes between 20% and 30% of real estate. There is not even a statistical argument for increasing that share for inflation-hedging purposes (Hamelink and Hoesli 1996).

A project's financial performance is, naturally, less important for social or revenue-driven developers. Still, two-thirds of the latter require a minimum return, typically 5% or 6%, while the other third demand at least that their costs be covered (Table 11). Social developers are split between cost coverage and applying the authorities' regulation (e.g. for subsidized housing), which generally allows for a small return on equity.

Table 11: Profitability requirements for social or revenue-driven developers, based on 2004 survey

	Social	Revenue driven
Does not need profitability, just cost coverage	44	36
Applies the criteria of the authorities	44	2
The return must not lie below some rate	18	63
No consideration whatsoever of profitability	4	0
Other profitability targets	4	6

Notes: Answers of 45 social and 84 revenue-driven developers. Several answers allowed. Column percentages.

In summary, about half of the investor developers are profit driven, mainly individuals and pension funds, one-third are revenue driven, mainly construction-related firms but also individuals, and one-sixth are social, mainly cooperatives and other non-profit developers. Half of the investor developers initiate a housing development when an interesting project is proposed or the circumstances are favourable for a piece of land they own; the other half seek projects for the investment opportunity, for the revenue or to address housing needs. Profit-driven developers generally perform a more or less sophisticated financial analysis of a project but less than half seek profitability first. The safety of a long-lived real asset is more important for small profit-driven developers. Thus, of 100 profit-driven developers, only 13 grade a project relative to their portfolio; 74 require a minimum rate of return but for only 20 is profitability compared to other investments their prime interest. Two-thirds of revenue-driven developers also require some minimum rate of return, whereas social developers are generally happy with cost coverage.

CONCLUSIONS

We probed developers' sophistication in computing the performance of residential investments: Are they forward-looking? Do they weigh risks against returns? Do they assess risks within their portfolios? We probed social developers about the attention they pay to profitability. We also surveyed developers about the intensity with which they seek new projects and the frequency with which they develop projects.

The picture that emerges is that of a heterogeneous population of housing developers. This resembles Beer's (1999: 260) finding from his study of private sector landlords in Australia, that 'individuals invest in rental housing for disparate reasons […] there is therefore a degree of unpredictability within the private rental market, not all investors are likely to respond quickly to changes in investment regimes or market conditions and this is particularly true for those on lower incomes'.

In our survey, the population of housing developers ranges from individuals who develop a project once in their lifetime to exploit the potential of a piece of land they may have inherited to quite sophisticated investors who are continually looking for opportunities to complete their portfolio. The occasional developers are about as important on the market as the repeat developers and private persons supply almost as many dwellings in multi-family units as construction firms and real estate companies together. In that configuration, it is not surprising that every second housing development was initiated for fortuitous reasons. Of course, it is never quite fortuitous that a project is proposed to a developer or that the circumstances become favourable for a piece of land, but the model of the professional developer who continually scans the market and attempts to catch every business opportunity describes only a small part of the market.

At the end of their survey of UK landlords, Scanlon and Whitehead (2006: 23) found: 'Given landlords' general insensitivity to developments in other markets, and the transactions costs problems, it is perhaps more useful to think of landlords as small businesspeople rather than straightforward investors.' This is even more true of housing developers as so many of them indicated as their main motive for housing developments the need to occupy their idle resources. This was less important in the mid-1990s, when housing construction peaked, than in the late 1990s, when it was in a trough. Overall, about half of the dwellings built for sale were built by construction-related firms that primarily sought the revenue. So were many rental dwellings that remained in the ownership of their developers. In earlier periods and other sectors (typically the office market), that development motive has led to overproduction and a protracted excess of vacant spaces. The Swiss housing market of the late 1990s would have dried up even more if it were not for the resilience of the construction firms.

Non-profit developers, who are commonly expected to buffer the withdrawal of traditional developers despite housing shortage, account for only one-sixth of the market. The near full elimination of public housing aid at the turn of the century (Kemeny *et al.* 2005) certainly did not help that category of developers.

With much fewer than half of the housing development projects initiated on the basis of an analysis of housing demand and predicted profitability, it seems preposterous to expect that housing supply reacts to market signals and incentives. It still does because the cues many developers use in place of a thorough feasibility study are not insensitive to market conditions. Thus, when half of the market developers require the sale of a minimum share of the dwellings before they launch a project, that condition is of course more easily satisfied when housing demand is strong. Equally, when half of the investor developers primarily seek the safety of a long-lived asset, they are certainly not blind to the vacancy rate, which is a strong signal of that safety. On the other hand, they may be quite sensitive to reforms that threaten that safety, such as a revision of rent regulation or land planning.

With such a heterogeneous population of housing developers, it is difficult to craft a policy that could help Switzerland retrieve more 'natural' housing vacancy rates than the current 1%. Avoiding unnecessary uncertainty, e.g. over rent regulation, is clearly a part of it. Acknowledging the large contribution of individuals is another one.

ACKNOWLEDGEMENTS

This research was supported by the Swiss Federal Housing Office. I am grateful for comments by Michael Ball and two anonymous referees.

NOTES

[1] More about the Swiss housing market and housing policy can be learned from Kemeny (1995), Lawrence (1996), Werczberger (1997), Thalmann (1997), Hauri *et al.* (2006) and the annual RICS European Housing Review.

[2] This little known fact is not that unusual: a majority of rental dwellings also belong to private individuals in the UK, Denmark, USA and Australia (Scanlon and Whitehead 2006).

[3] Scanlon and Whitehead (2006) made a similar distinction between 'professional' and 'non-professional' landlords. The former own at least three properties; their letting income is at least half of their total income; and they declare financial, business or pension motives for being a landlord. Thus defined, professionals make up 15% of their sample of buy-to-let customers with outstanding mortgage debt in the UK.

[4] Mortgage debt owed by private households residing in Switzerland is 75% of GDP in 1999. Typical financing of housing property is 80% mortgage debt and 20% equity. The mortgage debt is amortized to 60% or 65% of the property's purchase price over 10 to 20 years and generally no further.

TORNADO SHELTERS AND THE HOUSING MARKET

Kevin M. Simmons[1] and Daniel Sutter[2]

[1] Department of Economics, Austin College, 900 N. Grand Avenue, Suite 61591, Sherman, TX 75090-4444, USA
[2]Department of Economics and Finance, University of Texas - Pan American, Edinburg, TX 78541-2999, USA

Mitigation against natural hazards often involves long-lived, immobile investments. Homeowners must be able to capture the present value of future benefits to equate the private and societal return on mitigation. The capitalization of mitigation into home prices thus is crucial for homeowners to have a proper incentive for mitigation. We investigate the existence of a premium for tornado shelters using home sales in Oklahoma City, where the deadly tornado outbreak of 3 May 1999 and the Oklahoma Saferoom Initiative increased public awareness of tornado shelters. We find that a shelter increases the sales price of a home by 3.5% to 4% or approximately $4200 given the mean price of homes sold in 2005. The magnitude of the premium is plausible given that shelters retail for $2500–$3000 installed.

Keywords: natural disasters, prices, tornado shelters, mitigation, multiple regression.

INTRODUCTION

Natural hazards threaten people and property. While commonly described as “Acts of God,” the choices people make about where and how to live - the built environment - significantly affect natural hazards’ impact on society (Mileti 1999). Numerous measures can reduce the impact of hazards, from the standpoint of economic efficiency; society should invest in the level of mitigation that minimizes the sum of hazard costs plus mitigation costs. Many scholars suggest that society undertakes too little (or an inefficiently low level) of mitigation. A recent analysis found that the benefit-cost ratio of Federal Emergency Management Agency (FEMA) mitigation exceeded four to one (Multihazard Mitigation Council 2005), suggesting (but not proving) that additional investment in mitigation would have yielded net benefits.

We examine one specific mitigation measure in this paper, tornado shelters. Tornadoes are nature’s most violent storm, and particularly prevalent in the Great Plains’ “Tornado Alley”. Storm cellars have a long history in the area, but engineers over the past 30 years have developed new underground tornado shelters and above-ground safe rooms capable of withstanding the most powerful tornadoes. In the 1990s, FEMA included tornado shelters in its National Mitigation Strategy and issued design standards for shelters and safe rooms (FEMA 1999).

Tornado shelters, like other types of mitigation – strengthened construction or elevating structures out of a flood plain – require an upfront investment. Builders and homeowners will be reluctant to invest in mitigation if unable to recoup some of the cost in the form of a higher price for a home or building. But will homebuyers care enough about natural hazards to pay extra for mitigation? We test for a house price

[1] ksimmons@austincollege.edu

premium for tornado shelters in single family homes in the Oklahoma County. Oklahoma City affords an excellent opportunity to test for such a premium due to high tornado risk, high public awareness of the risk, and an inventory of homes with shelters. The inventory of shelters is due in part to the Oklahoma Saferoom Initiative, sponsored by FEMA and the State of Oklahoma after the 3 May 1999 tornadoes. The program offered $2,000 rebates for shelter or safe room installation and received more than 14,000 applications and paid out rebates for 6,400 installed shelters. If a price premium exists for tornado shelters anywhere, it should be in Oklahoma.

We analyse county tax assessor records of over 13,000 home sales in the Oklahoma County area in 2005. Over 400 homes, almost 2.5% of the sample, have tornado shelters. Homes with shelters are available in all size and price categories and not only for the rich buying luxury homes. Homebuyers should be able to find a home with a shelter and other desired features as well. A hedonic regression analysis reveals that homes with shelters sell for 3.5 to 4 percent extra than a comparable home without a shelter, a premium of about $4200 for the average priced home.

The remainder of this paper is organized as follows. Section 2 lays out the theoretical issues regarding the market value of mitigation and reviews relevant previous research. Section 3 provides variable definitions and summary statistics. Section 4 examines the characteristics and location of homes with shelters in greater detail. Section 5 presents our regression analysis. Section 6 offers a brief conclusion and directions for future research.

MITIGATION AND HOUSING MARKET: RELEVANT LITERATURE

Like many types of natural hazards mitigation, tornado shelters are a long-lived, immobile form of self-protection (shelters reduce the probability residents are killed or injured in a tornado, but do little to reduce damage and thus are self-protection instead of self-insurance (Ehrlich and Becker 1972)). A safe room is built into a home and cannot be moved, while the cost of digging up and moving an underground shelter is comparable to installing a new shelter. The resident making the installation is unlikely to personally consume all of the protection of the shelter or safe room, which could have a useful life of over 30 years. Residents may consider only the safety benefits during the time they plan to live in the home and ignore the remaining benefits from the shelter. Due to these spillover benefits, society may experience an inefficiently low level of investment in tornado protection (Kunreuther and Kleffner 1992).

This time horizon problem can be overcome if the shelter purchaser can sell the home at a premium reflecting the value of remaining safety benefits. The homeowner can then capture the full benefit to society of the shelter and can compare the benefits during the period she expects to live in the home with the net cost of the shelter. Premiums for shelters (and other amenities or a well-maintained home) are crucial to an efficient housing market.

Several problems can complicate the sale of homes with tornado shelters at a premium. A first problem is transactions cost. If only a small percentage of buyers value shelters, matching buyers interested in shelters with homes with shelters may be difficult. In the limit if almost nobody valued shelters, they would represent vanity items with no market value. Also buyers interested in a shelter may face a limited range of choices and have to decide between a house with all their desired features except a shelter and a much poorer matched house with a shelter. A poor match with other features reduces the equilibrium premium.

A second problem is buyers ignoring tornado risk altogether in purchasing a home. Many studies have demonstrated the existence of a low probability, high consequence event bias in decision making, people treat the small probability of a tornado or other hazard as zero (Camerer and Kunretuther 1989). When people ignore tornado risk, the perceived value of protection (or mitigation) is zero, even though the same persons might choose to buy a shelter if they perceived the true probability of a tornado. (Note though that Peacock (2003) points out that homebuyers are often quite concerned with hazard risk when looking to buy a home but often lack extra cash after purchase to invest in mitigation.) In addition, some homebuyers will be new to tornado prone areas and consequently unaware of tornado risk in their home purchase decision. Demand for homes with shelters and the market premium falls as the percentage of buyers who ignore tornado risk increases.

Third, potential buyers might exhibit myopia (Kunreuther and Kleffner 1992). Mitigation typically involves upfront expenditure and produces benefits over the useful life of the measure. Myopic individuals focus on the initial cost (or apply too high of a discount rate) and choose not to invest in mitigation measures which seem to have positive expected value. Thus, homebuyers may see the higher price of a home with a shelter and excessively discount the benefits. Kunreuther (1998) argues that financing mitigation through a mortgage or home improvement loan should offset myopia since people can compare the annualized cost with the annual benefit. Since a premium for an existing shelter is included in the sale price of the home and can be financed in the mortgage, myopia may not be a severe problem for tornado shelters.

Economists have estimated hedonic models of home prices for many decades. The technique has been employed, for example, to confirm the impact of environmental factors like air and noise pollution on home prices. Most applications with respect to natural hazards have investigated the impact of risk or risk perception on home prices as a test for low probability event bias. For example, Brookshire *et al*. (1985) and Beron *et al*. (1997) found that homes in seismic zones designated by the state of California sell at a discount, and that the size of the discount declined after the 1989 Loma Prieta earthquake. Shilling *et al*. (1985), MacDonald *et al*. (1987) and Spreyer and Ragas (1991) all found that homes located in flood plains in three different Louisiana cities sold at approximately a 6% discount relative to homes out of the flood plain. Hallstrom and Smith (2005) and Carbone *et al*. (2006) examined the impact of Hurricane Andrew on home prices in two Florida counties, Miami-Dade and Lee. The growth in house prices declined after Andrew in areas of each county most susceptible of storm surge flooding, consistent with a greater perceived risk of hurricanes throughout the state. In all cases, these studies found that participants in the housing market were aware of and responded to the natural hazard risk. Relatedly, Ewing *et al*. (2007) found that powerful tornadoes and hurricanes lowered a housing price index in the affected metropolitan area by 0.5% to 2% in the quarter of the event, but have no permanent effect on house prices. Thus, both natural hazards risk and hazard events can affect home prices, although none of these studies examined mitigation of homes facing a hazard risk directly (restricting building in or relocating homes out of a flood plain is a type of mitigation).

Two studies have applied hedonic price models to examine whether housing markets value natural hazards mitigation. Simmons, Kruse and Smith (2002) found a statistically significant 5% price premium for houses with hurricane blinds in a Texas Gulf coast city. The price premium approximately covered the full cost of hurricane blinds for the average home in their sample. Simmons and Sutter (2007) found a 5% premium in lot rents for tornado shelters in manufactured home parks in Oklahoma. For the average park in their sample, the rent premium would approximately cover the cost of an underground shelter. Their result, however, just failed to attain statistical significance.

Several studies have examined the value of shelters in tornado prone areas, which affects the likelihood of detecting a house price premium. Simmons and Sutter (2006) find that the cost per life saved for tornado shelters in Oklahoma exceeds $50 million (the calculation assumes a 3% discount rate, $2,000 cost per shelter, and a 50 year useful life of a shelter), while market revealed values of a statistical life rarely exceed $10 million (Viscusi *et al*. 2000). This suggests that with full information about tornado risks relatively few households will be willing to pay very much for shelters, leading to the transactions costs problems discussed above in matching the small proportion of home buyers interested in shelters with the small proportion of homes with shelters. Two studies have directly estimated the value of shelters using the contingent valuation method. Ozdemir (2005) in a survey of residents of Lubbock, Texas found that the mean willingness to pay for shelters was $2449, while Ewing and Kruse (2006) found a mean willingness to pay of $2500 in a survey of Parade of Homes visitors in Tulsa. Willingness to pay reflects residents' subjective perception of tornado risk and preferences toward risk, while Simmons and Sutter's cost per life saved uses an objective measure of risk – actual tornado fatalities. Buyers' actual willingness to pay will drive the market premium for shelters, so we may find a market premium even though objective risk data suggests that the premium is likely to be small.

VARIABLE DEFINITIONS

Our data set consists of sales of single-family homes in 2005 in Oklahoma county in the Oklahoma City metro area. We omitted properties with areas of less than 700 square feet or a sales price of less than $10 per square foot, and one home that sold for over $11 million, or more than three times the price of the next most expensive home. We have a data set of 13,461 home sales. The sales data for each county are from publicly available Tax Assessor records. Our data set is cross-sectional and thus unfortunately does not allow analysis of repeat sales of the same property, which would control for immeasurable characteristics of the homes.

Our variable of interest is *Shelter*, a dummy variable that equals one if a home has a tornado shelter or safe room and zero otherwise. Local officials and emergency managers in each county have created an inventory of tornado shelters over the past several years. The inventory combines building permits, rebates awarded as part of the Oklahoma Saferoom Initiative, a property tax exemption for shelters passed by voters in a referendum in November 2002, and self-registration by home owners with emergency managers. The inventories are considered reasonably complete and include the date of installation if a building permit was issued. (For shelters installed during 2005, the date of installation was compared with the sales date to determine if shelter installation preceded the sale. The inventories of shelters distinguish between shelters and safe rooms, but there were too few safe rooms to investigate a separate effect of shelters and safe rooms. Data were also obtained for Cleveland County in the Oklahoma City metro area, but the inventory of tornado shelters appeared quite incomplete (only 6 of over 5,000 homes sold in 2005 were reported to have shelters), and thus we estimated the models using only the Oklahoma County data.)

The dependent variable is the natural logarithm of *Sales Price*, the price in dollars. We employ White's robust standard errors in our regression. Table 1 reports summary statistics for our data set. The average sales price was $119,400, with a range of $8,000 to $3.1 million. Just over of half the homes in the data set sold for less than $100,000, while 11% sold for over $200,000. Figures 1 and 2 display the distribution of home sales prices for all the homes and for homes with shelters.

Table 1: Summary statistics

	Mean	**Standard Deviation**	**Minimum**	**Maximum**

Baths	1.74	0.6857	1	7.5

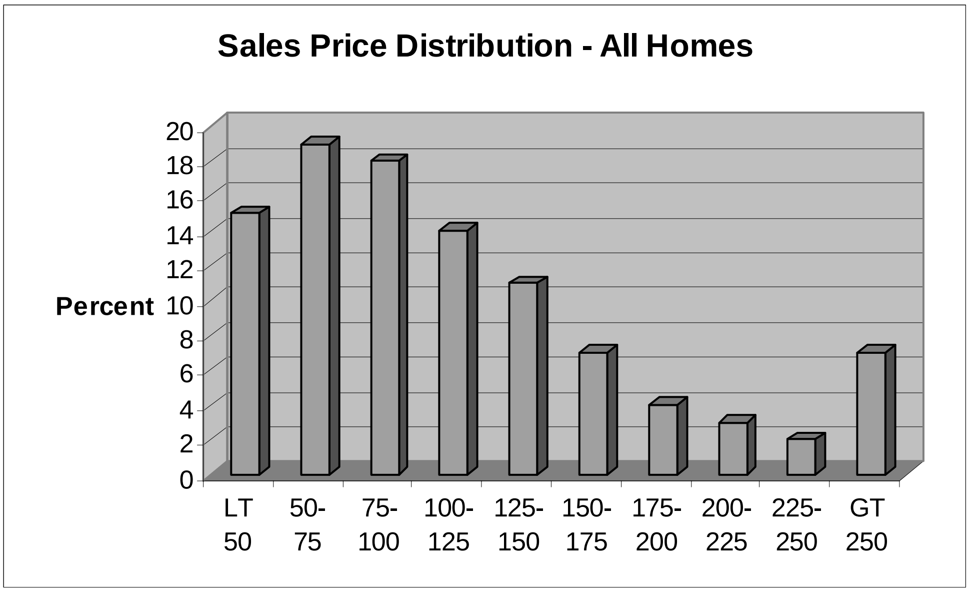

Figure 1: Sales price distributions of homes

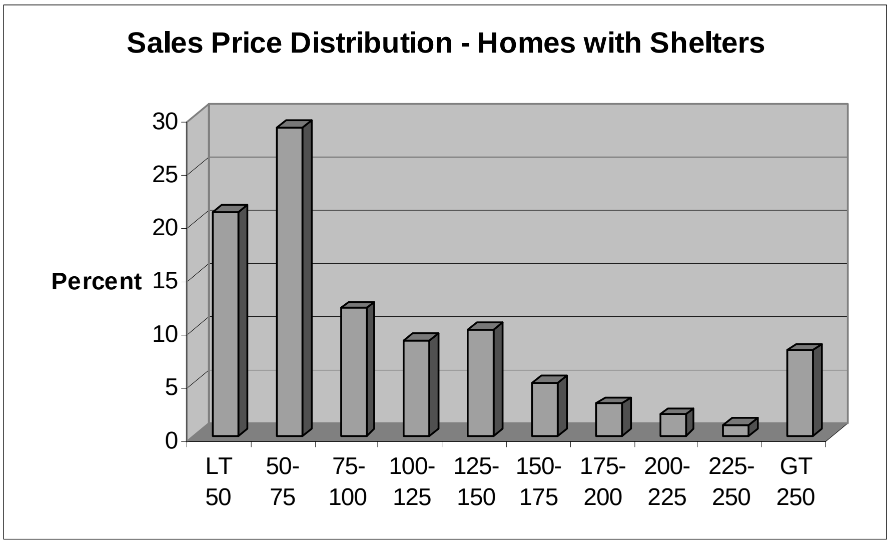

Figure 2: Sales price distribution of homes with tornado shelters

We employ numerous control variables constructed from the Tax Assessor's records. Our basic model for the control variables follows Simmons *et al*. (2002), limited by the exact home characteristics tracked by the Oklahoma County Tax Assessor. *Age* is the age of the home in years in 2005, or 2005 minus the year the home was built. The oldest home in our sample was built in 1860 while 548 homes were built in 2005. The mean age of homes is 38.8, or the average home was built in 1967. About 20% of homes are 10 years old or less, while 28% of homes are over 50 years old. We expect older homes to sell for less, everything else equal (we replace zero with .001 when taking the natural log of *Age*). *Square Feet* is the size of the home. Our mean home size is 1620, with a range from 700 to 13,395. We expect larger homes to sell for a higher price. In addition to *Square Feet*, the Tax Assessor records report three attributes of home size, *Rooms, Bedrooms* and *Baths*. While these variables are all positively correlated with each other and home size. Given the correlation between the variables, we include only *Baths* in our regression.

Our data set contains seven dummy variables describing a home's exterior and four dummy variables describing the roof. The exterior variables are *Asbestos, Brick-Veneer, Hardboard, Masonry, Siding, Vinyl* and *Other Exterior*, while the roof variables are *Hip, Gable, Hip/Gable* and *Other Roof.* All of these variables were constructed by the authors from the Tax Assessor records. We omit *Masonry* and *Hip* in our regressions, so the coefficients on the included variables show the effect of each exterior or roof type relative to these categories. We have no expectations about the signs of these variables, which we include as controls.

We include a number of dummy variables to control for location. About 65% of homes sold in 2005 were in Oklahoma City, so we include a dummy variable *OKC* equal to one for homes in Oklahoma City and zero otherwise. We also define a set of zip code dummy variables for each of the 51 zip codes included in our data set. These variables should control for differences in local neighbourhood housing markets. In addition, we include a set of dummy variables for the month of sale of the home. Both the zip code and month dummy variables were jointly significant, but to conserve space we do not report them in our regression tables.

A CLOSER LOOK AT HOMES WITH TORNADO SHELTERS

Before turning to our econometric analysis, we first examine the characteristics of homes with tornado shelters in some detail. A problem for our empirical analysis would arise if only large, expensive, new homes had shelters. In this case, a shelter premium could actually be a premium for luxury homes, particularly if our control variables fail to adequately capture the features of upscale homes. The distribution of shelters across types of homes also affects societal vulnerability (Peacock 2003). If tornado shelters were only available in half million dollar, 4000 square foot homes, few people could afford a house with a shelter, and policy makers might consider taking steps to make shelters available for working class families.

Table 2 presents the mean values of several variables for homes with shelters. The table also indicates if the mean significantly differs from the population mean. A simple mean comparison shows no evidence of a price premium for shelters, as the mean sales price for homes with shelters is $109,000, compared with $119,000 for all 2005 home sales, a difference that is statistically significant at the 10% level. The comparison certainly indicates that some average and below average priced homes have shelters. Closer analysis shows that 21% and 41% of homes with shelters sold for under $50,000 and between $50,000 and $100,000 respectively compared with only 15% and 37% of all home sales in these price ranges. Clearly, buyers in all price ranges can find homes with tornado shelters.

Table 2: Characteristics of homes with shelters

	Mean	Standard Deviation	Minimum	Maximum
Sale Price	108,791	96,326	12,500	635,000
Shelter	1	0	1	1
Square Feet	1,484	753	700	4,917
Age	41.9	22.5	0	100
Masonry	0.6123	0.4878	0	1
Asbestos	0.0617	0.2410	0	1

Other	0.0148	0.1210	0	1
Hip	0.2494	0.4332	0	1
Gable	0.5012	0.5006	0	1
Hip/Gable	0.2444	0.4303	0	1
Other Roof	0.0049	0.0702	0	1
Rooms	5.72	1.3616	2	10
Bedrooms	2.84	0.6759	1	5
Baths	1.58	0.7174	1	4.25

We might expect that only large, new homes would have tornado shelters, but Table 2 shows this is not true. Homes with shelters were on average three years older and 140ft^2 smaller than all homes sold in 2005. Again analysis of the distribution of homes by size and age confirms that a wide variety of homes feature shelters. Thirty percent of homes with shelters were less than 1000ft^2 and only 17% over 2000ft^2, while 19% and 23% of all homes sold fell into these categories. A total of 43% of homes with shelters were over 50 years old compared with only 32% of all homes sold. (The age of many of the homes with shelters raises the possibility that these older homes have unfinished basements or storm cellars and not modern shelters or safe rooms. The inventory of shelters does not control for quality or include only shelters built to

FEMA specifications. Ewing and Kruse (2006) find that people would be willing to pay $600 extra for shelters certified by the National Storm Shelter Association; we will control for old homes in our econometric analysis.)

Table 2 also reports the mean values of the room, exterior and roof variables for homes with shelters. Comparison reveals that homes with shelters have fewer *Rooms*, *Bedrooms* and *Baths* than the sample as a whole, with the differences being statistically significant at the 1% level. Homes with each category of interior and roof have shelters, so buyers should not have to sacrifice too many desired characteristics to buy a home with a shelter.

As mentioned above, almost all the homes with shelters in our sample were located in Oklahoma County. Overall, about 3% of homes sold in Oklahoma County had shelters. Our data set includes homes in 11 different cities within the county. The percentage of homes sold with shelters ranged across communities from 1.8% in Edmond to 6.9% in Del City, which was affected by the 3 May 1999 tornado and where many residents took advantage of the Oklahoma Saferoom Initiative. Homes with shelters are available throughout the county, so a buyer should be able to find a home with a shelter near their desired placed to live.

RESULTS

Table 3 reports our regression results. Column (a) contains the full model estimated on our entire data set. Our variable of interest, *Shelter*, has a positive point estimate, indicating a 3.5% price premium, and is statistically significant at the 10% level in a two-tailed test. The 3.5% price premium translates into a $4200 price differential for our average priced home. The magnitude is very reasonable given that underground shelters currently retail for $2500–$3000 installed, while above-ground safe rooms cost $5,000 or more. Note that this amount exceeds by about 67% the mean willingness to pay for a shelter or safe room of $2500 found by Ozdemir (2005) and Ewing and Kruse (2006).

Square Feet and *Age* perform as expected, with larger and newer homes selling for a higher price and both variables significant at better than the 1% level. Both of these variables enter in logs in our specification, and thus the coefficients are elasticities. Specification (a) shows that a 10% increase in area increases the sales price by about 9%, while a 100% increase in *Age*, say from one to two years, reduces price by about 2%. An extra *Bath* increasing the price by about 16%. Homes in Oklahoma City sell at a statistically significant 13% discount relative to the rest of Oklahoma county. Four of the exterior variables are significant at the 10% level or better, while none of the roof variables are significant at the 10% level, so buyers seem to place greater weight on the exterior than the roof.

The majority of homes in our sample are in Oklahoma City, and as a robustness check on our results, we report in (b) a specification of the model using only homes in Oklahoma City. This specification eliminates differences in local government services across jurisdictions, which may be imperfectly controlled for with the zip code dummy variables, as a possible explanation of our results. Note that the model also includes zip code dummy variables to control for neighbourhood effects within Oklahoma City. The point estimate of *Shelter* is a slightly larger 4.2% price premium than in (a). The point estimate fails to attain significance at the 10% level in a two-tailed test, although the estimate is significant at the 10% level in a one-tailed test. Overall the estimated coefficients of the other variables are virtually unchanged, with the only difference in significance that *Siding* is no longer significant, although its point estimate is slightly larger.

We noted earlier that 43% of homes with shelters were over 50 years old, and that some of these older homes might have storm cellars instead of modern shelters. Home buyers might not consider these equivalent to new shelters and safe rooms, and this might affect the estimated shelter premium. We do not know the age of the shelter, and so cannot control for old shelters directly. Consequently, column (c) presents a specification omitting homes over 50 years of age, which should exclude all vintage storm cellars. Omission of old homes has a modest effect on *Shelter*, which is now exhibits a statistically significant at the 10% level in a two-tailed test 4.0% price premium. The price premium for the average priced home is now approximately equal to the cost of an above-ground safe room. A few modest differences between the specifications with the full data set and with old homes are excluded. The coefficient on *Square Feet* is slightly larger with an elasticity now just less than one, while the coefficient on *Age* is reduced, and newer homes in Oklahoma City sell at a discount of just over 4%. *Vinyl* and *HipGable* now attain significance at the 5% level, while the overall fit of the model is slightly reduced (we also estimated the model excluding the 20 homes that sold for more than $1 million, but the results were very similar to (a) and so we do not report this specification here).

CONCLUSION

The 2004 and 2005 hurricane seasons increased public interest in mitigation measures capable of reducing losses from natural hazards. Mitigation often involves a long-lived, immobile investment. Homeowners who invest in mitigation may not capture all of the benefits of mitigation if they do not live in the home throughout the measure's useful life. House price premiums for mitigation must exist for the market to provide proper incentives for investment in mitigation.

We have investigated the existence of a premium for tornado shelters in the prices of homes in the Oklahoma City metro area in 2005. Consistent with Simmons *et al*. (2002) for hurricane shelters, we found a premium for tornado shelters. The *Shelter* variable is statistically significant at only the 10% level, although this would be at the 5% level in a one-tailed test, which would be appropriate if we did not expect that *Shelter* could reduce the sale price. The point estimate indicates a $4200 shelter premium for the average priced home in our sample, which exceeds the cost of underground shelters but is somewhat less than the cost of above-ground safe rooms.

One direction for future research would be a longitudinal study involving repeat sales of homes. Repeat sales analysis focuses on the change in price, and this avoids problems with unchanging but hard to measure factors affecting home prices (Hallstrom and Smith 2005; Carbonne *et al*. 2006). If repeat sales of homes before and after shelter installation can be identified, this would allow determination of whether a price increase can be attributed to the shelter.

Future research could also search for shelter *premia* in other real estate markets. Several factors made Oklahoma City particularly likely to exhibit a premium for tornado shelters: a high risk of damaging tornadoes, high public awareness of tornado risk and a sufficient inventory of homes with shelters. It may be unlikely to find a premium for shelters in other cities because the cost per life saved for tornado shelters in single family homes increases quickly even when comparing tornado prone states like Oklahoma and Texas (Simmons and Sutter 2006b). However, along the Gulf coast or in Florida, shelters and safe rooms also provide protection against hurricane winds as well, so safe rooms might carry a premium due to dual use in these areas.

SOCIAL SCIENCE RESEARCH AND CONSTRUCTION: BALANCING RIGOUR AND RELEVANCE

Chris Harty[1] and Roine Leiringer

School of Construction Management and Engineering, University of Reading, PO Box 219, Reading, RG6 6AW, UK

For construction management (CM) research, the challenge of linking academic research priorities with those of industry, and to generate the flow of knowledge between the two is crucial. It is also not straightforward. Here, the debate over academic rigour versus industry relevance, or bridging the 'relevance gap' is discussed specifically with respect to CM social science oriented research. We argue that the relationship between the two is complex, and to position them as polar opposites is a misleading oversimplification. We identify other actors and institutions which also influence the generation of research questions and outputs. The argument is made that the landscapes of academia and industry are reflexively and recursively linked rather than separate and distinct, especially in an applied field such as CM. It is through exploring these connections and interactions and the practices and ideas which emerge from them that relevance and rigour can be best understood.

Keywords: relevance, research methods, rigour, social science.

INTRODUCTION

Across much social science research, including construction management and management more generally, the challenge of linking academic research priorities with those of industry, and to generate the flow of knowledge between the two is considered crucial. Academic research uses real world contexts as sites for both developing research questions and conducting empirical study to examine them. In return for such access, researchers make claims that research outputs will have utility outside academic domains. Without such promises of exchange, the relationship between research and industry becomes essentially parasitic, which does little to develop good relations between the two. As well as the need for reciprocal relationships, developing effective connections between academia and industry is prioritized at the highest levels. The 1993 government White Paper *Realising our potential: a strategy for science engineering and technology* called for

> closer partnership and better diffusion of ideas between the sciences and engineering communities, industries, the financial sector and Government … as past of the crucial effort to improve our national competitiveness and quality of life (HMSO 1993: 8).

But although the rhetoric of users and industry collaboration permeates construction management funding priorities calls and proposals, relationships between academia and industry are beset with difficulties. HEFCE, in their *Industry–academic links*

---

[1] c.f.harty@reading.ac.uk

report (Howells *et al.* 1998) outline some of the ways that these manifest themselves. Among other things the report contends that:

- although industrial actors believe that research can be beneficial, few research topics are seen as focusing on key issues of relevance to them;
- managers feel that research does not directly contribute to their activities. In order to do so, prescriptive statements and best practices which can be implemented are wanted, over reflexive analysis;
- industrial sectors lack awareness of research and research results. Researchers lack effective methods to disseminate results.

These statements imply the existence of significant differences between academic and business contexts, that interests do not overlap and that no effective means or mechanisms of knowledge sharing are evident. It is therefore not surprising that the highest ranked barriers to higher education institutions producing effective links with industry were identified as ‘differences in objectives’ and ‘work needed by industry not interesting’.

The HEFCE report is not in isolation in drawing these kinds of conclusions. Similar findings and views aired elsewhere have prompted a debate within management literature of how to satisfy the double hurdles of being relevant to industry and maintaining academic rigour, or of bridging the ‘relevance gap’ between the two.

The debate is not just about finding a median point between the ivory towers of academia and the hard-nosed world of business. It includes a number of issues such as: the extent to which research should act as a problem-solving ‘service’ to business sectors; the importance of research being disconnected from current business concerns in order to develop novel ideas, processes and products; alternative ways businesses might generate relevant knowledge; and, importantly, the different sorts of epistemological positions being implied.

We contend here that a major stumbling block in attempting to understand the relationship between relevance and rigour is falling into an easy opposition between business and academic worlds. This assumes that there is a clear-cut distinction between the two, and that each is a homogeneous entity with recognizable similarities and shared priorities. This is, of course, far from the reality of the situation where researchers must continually satisfy a number of different bodies if they are to ‘do’ relevant and rigorous research. These include academic peers, funding bodies and industrial partners, each of which has their own priorities, peculiarities and paymasters. Much can be made of the rhetorical aspects of, for instance, convincing funders that research effectively reflects and addresses non-academic priorities, or in enrolling industrial partners with promises of relevance, while continuing to pursue mainly academic priorities. However, as well as reproducing the notion of a relevance gap this strategy would also seem to be unsustainable in the longer term, especially in the sense of keeping industrial partners interested and involved. A question that remains unanswered is what actually counts as useful research within these different domains?

This paper explores these issues, drawing on wider management and social science literatures but in relation to social science oriented UK construction management research. The aim is to illuminate some of the key interactions that constitute CM research, which incorporates numerous academic and industry actors. To begin, the polarization of relevance and rigour is questioned and evidence for the overlapping or merging of industry and academic terrains is discussed. The notion of 'playing the game' of relevance and rigour is explored, as are the relationships between research and enterprise and research and teaching within university institutions. The different epistemological lenses mobilized and forms of knowledge required and produced by different actors are discussed, including the distinctions between Mode 1 and Mode 2 knowledge production. A case is made for seeing academic and industry domains as reflexively linked, not distinct and separated by any relevance gap.

RELEVANCE AND RIGOUR IN CONSTRUCTION MANAGEMENT RESEARCH

Within CM as well as more widely, the academic rigour of research has largely been shown through publishing in refereed journals. The reviewing and refereeing process, undertaken by academic peers, ensures that what gets through demonstrates the required level of scholarly content. It traditionally operates in parallel with any industry or policy oriented report writing and dissemination that research projects generate. However, this seems to be changing, and there is evidence that relevance and rigour cannot be sustained as contrasting aims. Within construction publications, McCaffer (2007) recognizes that there is a clear trend towards demands of demonstrating research's impact upon industry. He states:

> the issue is if research has no impact (and I don't mean citations) then what is it worth. [sic] ECAM [Engineering, Construction and Architectural Management] should lead the field in asking authors to address the impact of their research more than we have. In effect academics are responsible for the implementation of their research and must be seen to be succeeding in this (McCaffer 2007).

McCaffer, then, suggests that the fundamental criteria of a good refereed paper are shifting towards its impact on industry. What is clear is that the notion of impact further serves only to muddy the waters of relevance and rigour. A relevance gap allows researchers to align their research around two distinct poles; one regarding its relevance and one regarding its rigour. This might be somewhat difficult to achieve in practice, but offers clear targets, if nothing else. A shift towards impact on industry as a mark of an academic paper's quality conflates these two positions. What does this mean for the rigour of construction research and research papers? How can their relevance be academically demonstrated? Without the convenience of a polar opposition between relevance and rigour the job seems even more difficult.

We might also ask who the ultimate beneficiaries of research are supposed to be. Relevant research could benefit individuals, single firms, sectors, 'industry' as a whole, 'the economy' or 'society' more generally. It is therefore problematic to conceptualize the directions of the research and the beneficiaries thereof as unidirectional or asymmetrical. The term 'impact' thus lends itself to a significant degree of subjective interpretation. A strong idealistic case could be made for the need of judging what research is deemed useful to society to be collectively determined rather than basing it on its impact on the specific business interests of companies. In contrast, it is tempting to follow the path of least resistance and comply with external pressures, aligning research with business priorities.

There is no doubt that CM researchers are sensitive to the larger contexts in which sectors, businesses and other institutions such as universities and research councils operate and how research is positioned within them. The UK construction sector has a long history of reviews which bemoan its performance and reports and policy documents prescribing change are constantly circulated throughout industry and academia. Over the past decade or more such a change agenda has been determined by an incessant mantra of modernization (cf. Fernie *et al*. 2006). Reproduced and supported by government and industry leaders it constantly reiterates the notion that research in the construction domain is only valid if it is industry centred and driven by the need for change. Riding along on this undercurrent comes a plethora of fads and fashions which, although viewed with some scepticism by many academics, have a great deal of currency within business contexts. It becomes rather tempting for researchers to position their research within this popular mantra for change, and to have recourse to such fads and fashions as are current at a particular time. Such compliance at times might come at the expense of the rigour of such approaches. Furthermore, it fails to acknowledge or discuss the implications of academic research offering advantage to one constituency at the expense of another.

It is necessary to keep in perspective that some of the statements made above are generalizations and run the risk of being overly simplistic. It would, for example, be naïve to state that CM researchers share the same ideas about the sort of product that their work generates, its effects on policy and practice and indeed how it contributes to knowledge. Such differences between researchers have led to a variety of distinctions being drawn between various approaches to research.

One important distinction is that between rational–instrumental modes of research rooted in the sciences and ‘pure’ engineering, and more subjective and qualitative approaches to construction management appropriated from disciplines such as sociology. The former ‘engineering model’ positions research as revealing something ‘true’ about the world it focuses on. This goes equally for research on the strength of particular materials as it does for economic modelling of construction processes. The intention is that by revealing something of reality, tools to help can be developed and implemented to predict, improve or exploit it. These might be in the form of stronger reinforcement materials, ‘best practice’ advice or new IT systems for managing workers. In terms of social science research in this tradition the findings are considered to be widely applicable in relatively predictable ways with identifiable and beneficial results.

By contrast, the latter more subjectivist approaches eschew the notion of a single objective reality in favour of seeking to understand how different realities and perspectives are locally constituted. This sort of research is interested in how meaning and values are derived, and how interactions between actors and material artefacts develop as they occur, and the practices and ideas that emerge from them. Any claims for the utility and applicability of knowledge or insights generated from this type of research would tend to be more modest than those within the harder engineering paradigm, with little expectation of wide generalizability or easily transferable results. This means that claims of relevance and impact on industry become more difficult to assess.

As an applied field construction management is populated by researchers subscribing to both of these approaches. This is obviously a positive quality, but can lead to attempts to judge more subjective research with harder measures. The relevance of a best practice guide is easy to ascribe if the engineering perspective is the one taken; judging its relevance from a more critical perspective entails a more involved discussion of the sorts of contexts in which research-generated knowledge has to make sense.

PLAYING THE RESEARCH GAME

One way to approach relevance and rigour is to think about the undertaking of research as playing a game with numerous different parties involved. It seems eminently sensible to suggest that academics routinely wear different hats in order to engage with different audiences. However, in order to do this, research must inherently have a certain amount of ‘interpretive flexibility’ (cf. Bijker 1992) to allow it to be shaped or mutated in different ways according to its intended audiences. Following from this, beneath this flexibility must lie core research activities which represent the real and autonomous interests of researchers. Questions then arise of precisely how much flexibility the ‘core’ research inherently has and to what extent the shaping of research ideas can be separated from the research process itself. It is possible that in attempting to satisfy multiple audiences, the research itself becomes somewhat diluted or stretched, and thereby loses or changes its focus. This has been highlighted at an institutional level by Elzinga (1985) as ‘epistemic drift’. As the priorities of academic institutions shift in responding to new external pressures, for instance demands from government to engage more with industry or to demonstrate the non-academic relevance of research, so too do their research agendas and research processes.

This drift is positioned by Elzinga as a watering down of the academic content of research and as constituting a change in the nature of the research being produced. The underlying argument that academic research should not be influenced by non-academic pressures might, however, be both misleading and misguided. Pure academic research with no connection or influence to any external factor is probably nothing short of a fiction. For good or ill, non-academic priorities do influence research agendas and activities. Through the wearing of different hats, the ideas and activities of the wearer are transformed.

Breslau (1997) offers a complementary perspective and proposes that it is perhaps more useful to look at how recognition is gained in contrasting social arenas, rather than looking at the outputs produced by research. He refers to Bourdieu’s (1986) concept of ‘capital’ and to the suggestion that individuals work to amass various forms of capital (e.g. economic, cultural, etc.), which have significance within different fields. Breslau develops the idea that ‘credibility’ constitutes one such form of social capital within business and academic domains. For research to be relevant and academically sound, it needs to be credible in both locations. The problem is that the mechanisms through which credibility is endowed are not the same in each. Within the academic field, established reputational sources of credibility are underpinned by a disciplinary structuring of knowledge and peer review. As such academia revolves around a number of more or less internally consistent relatively homogenous structures. In contrast, the status of research within the private sector is much more heterogeneous. Credibility is conferred by multiple external groups, including advisory panels, research funders, industry spokespersons and practitioners. In business (broadly defined), credibility comes from the practical (and non-academic) implications of research, and from its utility as a resource for controlling, influencing or understanding business contexts. The problem of relevance remains as one of satisfying plural demands, gaining the appropriate credibility in different locations. It is clear that the game that has to be played is different within these different landscapes.

Rooted in social science approaches Breslau then develops these ideas by comparing the ‘purer’ academic approaches of economists, with more ‘hands-on’ and qualitative approaches of sociologists located in ‘contract shops’ outside academia. In general researchers were found to seek to gain credibility in one or other domain but not both. Different strategies were employed in each case; ‘incorporation’ and ‘secession’ (*ibid*.). The strategy of incorporation is one in which research is positioned in relation to existing (disciplinary) knowledge and is judged by academic peers. Secession on the other hand involves rejecting these conventions, and dismissing evaluation by the scholarly community. The focus is instead on the extent to which research is grounded in local contexts and framed by the meanings and assumptions found within them. The ‘contract-shop epistemology’ of the secessionists facilitates a more interactive connection between research and contexts, using localized and qualitative approaches. But the implication is that this is at the expense of disciplinary rigour. Although Breslau highlights the socialized nature of the contexts of research and of the research process itself, his analysis still reproduces a gap between academic and external concerns.

Of particular note is the strong case he makes about the deep entrenchment of discipline-based practices and ways of thinking in the US university economics departments he looked at. This resonates strongly with the ideas of disciplinary structuring through reputation in the UK offered by Whitley (1984) as well as with other work on the problems of positioning and evaluating interdisciplinary knowledge (see Harty and Shove 2004; Shove and Wouters 2005). The calls for interdisciplinary approaches to real world problems made by research funders such as the UK research councils do not juxtapose easily with the disciplinary-based structures of academic assessment through journal publication. These disciplinary-based mechanisms are themselves reproduced by the present methods of the research assessment exercise conducted by those very same institutions calling for interdisciplinary approaches.

PLAYING THE RESEARCH GAME IN CM

The challenges in satisfying numerous demands are also evident in construction management. Yet, it must be noted that UK CM research has a particularly good record for getting research funded and in working with industry. Indeed, many researchers and research institutions pride themselves on developing and maintaining long-term relations. There also seems to be no shortage of academic papers being submitted to CM conferences and journals.

So how are the various sets of requirements and demands handled and played out in practice? The obvious answer is that research ideas and outputs from research activity are framed or shaped differently for different audiences, with each version telling its prospective audience something of what it wants to hear. Proposals are worded in specific ways to resonate with funders’ priorities and expectations; industry-focused documents tend to avoid jargon and be more concise. Papers are written with specific journals in mind, which can dictate not just format, but the positioning of the research, the sorts of literature cited and even the arguments developed. Within all of these, current fashions, hot topics and buzzwords might be used or alluded to as deemed suitable.

However, as well as the problem of drifting (epistemically or otherwise) away from core research interests, this would also invariably produce a certain degree of routinization of efforts. It is plausible to suggest that these means of assessment lead to the emergence of highly scripted approaches and outputs, especially if they have proved successful in the past. Kaplan (1964) discussed 'the law of the instrument'. Give a small boy a hammer, he argued, and he will find that everything that he encounters will need a pounding. While the metaphor is rather crude and it would be wrong to characterize researchers in the field as one-trick ponies, the above-described scenario would seem to generate instrumental approaches which resonate with accepted ideas and ways of forming and formatting research, rather than novel ideas.

Take, for example, the journal outlets available in the field. Many of these have word restrictions of between 3000 and 5000 words. As such it could be argued that they favour papers that are structured along the lines of the engineering model. While many researchers would not openly subscribe to this model they are still coerced to represent their research in this manner as it greatly increases their chances of getting published. Even without any political bias towards one or other method, the length allowed for papers means that, for example, detailed qualitative analysis is difficult to produce as it invariably requires more words to describe than papers based on more generalized and concise outputs. This same problem also applies to outputs oriented to industry. In all it encourages the production of the same sort of outputs over and over again. This has much appeal to the researcher as it generates the accumulation of publications which is crucial to individuals' CVs and appeals to the efficiency-led rationale of much of industry.

So it would appear that the playing of multiple games might adequately describe the activities of researchers, but that it is difficult to separate this from the formulation or transformation of research agendas, activities and outputs. Through concerted efforts to play the game, or through less direct processes like epistemic drift, ideas and outputs are constituted and transformed as they go through processes of funding, researching and publishing.

RESEARCH AND ENTERPRISE

As well as thinking about the different networks that individual researchers inhabit, and the activities they perform in getting funding and doing research, the wider institutional contexts in which they operate should also be considered. Universities are increasingly moving into areas such as spin-off commercialization of research outputs and consultancy. 'Enterprise' has become a key strategic theme – again muddying any waters that might once have reflected a clear divide between academic and non-academic priorities.

This means that in practice, construction management researchers have to sell their ideas (and themselves) to a range of potential customers in competition with other players in turbulent and increasingly overlapping marketplaces. It is not quite so simple as offering distinctive qualities or 'unique selling points' of academic research – which traditionally have tended to be its scholarly rigour; its particular (non-business-based) approach to understanding; and its commitment to long-term knowledge development. If firms subscribe to government opinion as outlined in the *Realising our potential* White Paper and see research output merely as a resource with which to achieve increased competitiveness or solve immediate problems these qualities are likely to have little perceived value. As indicated in the HEFCE report, practitioners seem to prefer knowledge packaged in the form of discrete, manageable chunks, for example as best practice prescriptions. Academic research is just one possible route to new knowledge production with others typically including consultancy, training and using the skills of in-house staff. What do academics really have to offer in these markets?

The solution to this conundrum does not necessarily lie in academic research getting ‘closer’ to the priorities and activities of industry. Many academics in construction management have, indeed, been critical of the overuse of instrumental approaches and an over-reliance on faddish concepts at the expense of substantive change (e.g. Green 1999; Bresnen and Marshall 2000). If some form of ‘contract shop epistemology’ is adopted, this critical function is in danger of being lost. This also potentially moves researchers away from the publication of scholarly papers, which so far has been an essential requirement for the advancement of any academic career. We arrive back at the same problems of incommensurability between academic and non-academic terrains.

RESEARCH AND TEACHING

It is also important to consider that research is not the only, or even the main, activity of universities. Teaching is central to a university’s success, and competition for attracting students is fierce. But this also brings with it inconsistent demands regarding the balance between academic and practitioner focus. Academic teachers and researchers are expected to respond to new and emerging problems and to engage with current non-academic priorities. At the same time, academic institutions are expected to provide a relatively stable platform of knowledge (i.e. textbook learning) in digestible chunks which informs and sometimes even constitutes the activities, problems and contexts of ‘management’ or ‘business’. The success of university institutions is largely governed by the attraction of students, which is itself at least partly a reflection of the employability of graduates with qualifications from specific schools or universities. But according to many managers, this type of teaching does not provide industry with individuals possessing the relevant skills to increase firms’ competitive edge. Higher qualifications such as MBAs have long been berated for lacking in providing transferable skills of use in the outside world (Linder and Smith 1992). Other issues, such as how less instrumental qualities such as entrepreneurship can be taught through devices such as lecturing (usually by non-practitioners) are also being raised (Binks *et al*. 2006).

This suggests that the standard model based on lecturing and written assessment is also failing to bridge the gap between academia and industry, although these opinions do not seem to have affected the demand for undergraduate degrees as a prerequisite for employment, or the bargaining power within industry offered through higher qualifications such as the MBA. So is the primary function of teaching to produce useful (and hence relevant) new construction managers for the industry? If so, where is the dividing line between imparting chunks of directly applicable knowledge through textbook learning, and developing critical (i.e. more academic) skills?

KNOWLEDGE FOR WHOM? THE EPISTEMOLOGICAL PRODUCTS OF RESEARCH

Thinking about the games played by researchers, the contexts in which they play and the consequences of the rules followed identifies a plethora of problems. However, what it does not do is bring us any closer to understanding the (dis)connections between the knowledge produced by academic research and what industry wants and considers useful. One explanation for this can be traced to the different epistemological lenses used by different researchers and by practitioners to frame and understand apparently similar problems and issues. This can culminate in a range of different accounts of the same problem, and ways to approach it.

According to some, firms have a particular lens or way of seeing their contexts which involves being only 'interested in the application of knowledge rather than knowledge for its own sake' (Starkey and Madan 2001: 6). This leads to a somewhat prescriptive-looking 'knowledge chain', designed to resolve specific problems effectively and efficiently through problem identification, data collection, decision making and solution.

This prescriptive view suggests that for academic research agendas to be relevant, they must engage directly with specifically business-oriented ways of framing and applying the knowledge they produce. A shared problem is not enough; research needs to be conducted and presented in ways which allow it to be evaluated by practitioners (decision making) and offer effective ways of implementing its insights (effective action). Neither is this an end-of-pipe question of repackaging academic (and by implication less relevant) knowledge. Again the gap looms large.

But although this unambiguously identifies a desire for specific, problem-solving knowledge, and bears similarities with the ethos of the engineering model of research, it also masks some more complex problems. For instance, where does the creativity and entrepreneurial skill desired by industry but apparently not produced through university education fit in? What about generating ideas to expand businesses in new and novel directions? How can potential problems be identified before they threaten competitive position?

NEW MODES OF KNOWLEDGE PRODUCTION

In response to this, some commentators argue that forms of knowledge production are themselves on the move. Starkey and Madan (2001) and Huff (2001) go along with Gibbons' (Gibbons *et al*. 1994) idea that recent years have seen the development of genuinely new forms of knowledge production. Looking (mostly) at the 'hard' sciences, these authors identify and trace the emergence of a new form of knowledge – Mode 2 – which departs from previous models of scientific knowledge – Mode 1 – in both structure and production. Mode 1 knowledge is discipline based: scientific method and theory development mattering more than practical implementation. In Mode 1 environments, the focus is on producing abstract and universal knowledge, not that which is specific, localized or concerned with practice. Mode 2 knowledge production is concerned with application and context;

> In Mode 1 problems are set out and solved in a context governed by the largely academic interests of a specific community. By contrast, Mode 2 knowledge is carried out in a context of application … In comparison with Mode 1, Mode 2 is more socially accountable and reflexive. It includes a wider, more temporary and heterogeneous set of practitioners, collaborating on a problem defined in a specific and localised context (Gibbons *et al*. 1994: 3).

The problems associated with Mode 1 knowledge production, with its separation from non-academic domains and its fixed notions of what does and does not constitute valid knowledge, are important constituents of the relevance gap.

So does a shift towards Mode 2 forms of knowledge production change anything? Representations of Mode 2 imply that strong links can be forged between theory and application, and that knowledge can be generated through the intersection of academic and non-academic priorities. Mode 2 therefore stands as an example of highly relevant knowledge production. It is not just an accommodation of the need for relevance, but is actively constituted by it through an interconnected 'triple helix' of industry, academic institutions and government. Thus, in theory at least, following a Mode 2 'route' will lead to insightful, relevant and accessible research agendas with widely useful knowledge emerging from them.

A fully functioning Mode 2 environment brings together the networks and markets positioned as distinct throughout discussions of relevance gaps. It supposes a degree of institutional restructuring involving the creation of new measures of academic impact, increasing the speed of knowledge production and establishing cross-disciplinary, practice-oriented, time-relevant associations and journals. Because of this, popular characterizations of Mode 2 environments are perhaps more aspirational than real, after all, existing cross- and interdisciplinary journals currently struggle to find audiences and to achieve similar status to disciplinary-based journals. Regardless of whether there really is a move towards Mode 2 or not, the institutions and practices of academic business research still show many of the hallmarks of Mode 1 knowledge.

RELEVANCE AND RIGOUR REVISITED

On a more abstract level framing Mode 2 as a response to problems inherent in Mode 1 involves trading one overarching model of knowledge production for another. In other words a Mode 2 framing supposes a 'new form of knowledge production', not multiple new ways of analysing or developing the subtle co-constitution of academic and non-academic priorities. Discussions of Mode 2 also generally suppose that changing the focus of research activity towards the real world problems of the private sector is a positive step, and that this is (at least part of) the real business of researchers.

With reference to management research, Pettigrew (2001) argues that the debate over forms of relevant and rigorous knowledge production needs to be broadened out, to:

> use the Mode 1–Mode 2 dichotomy to open up debates about the character, quality and relevance of the knowledge we produce, and not slip into the easy but shallow option of saying that the answer lies in Mode 2 (whatever that is in practice) (Pettigrew 2001: 62).

In other words, the practice of doing relevant academic research cannot be reduced to the adoption of Mode 2 (seen here as a way of working). Pettigrew goes on to identify other necessary ingredients for relevance, in addition to those of scholarly quality. These he lists as:

- Engagement with the social science and management literatures; at appropriate moments and with appropriate partners, combining knowledge production and use.
- Ensuring the internal development of the fields of management while engaging with co-beneficiaries and co-producers.

- Challenging and transcending the current beliefs and knowledges of those stakeholders we work with while also engaging with those beliefs.
- Preserving researcher autonomy as a precondition to build scholarly identity and creativity, while encouraging different forms of engagement with stakeholder communities.

This is a useful list, if somewhat idealized. However, Pettigrew does recognize that reconciling academic and practitioner worlds is no easy task. Each of these requirements constitutes one of the 'double hurdles' for management research. These hurdles involve more than simply maintaining parallel streams of research or dissemination in academic and business fields. Instead, Pettigrew argues that the two domains are reflexively linked. The pursuit of knowledge driven by abstract, intellectual problems can have direct implications for practice, for instance in providing concepts and models (e.g. theories of the market), which practitioners use to frame and understand the contexts in which they operate. Also, moving too far away from academic lines of enquiry runs the risk of disconnecting research and research agendas from wider social scientific debates. This is a trend Pettigrew detects in the increasing fragmentation and specialization of management research and which is equally important for CM research which also takes concepts, theories and methodological approaches from elsewhere. Maintaining the rigour of CM research also involves positioning it alongside other related areas, such as management research or the social sciences.

CONCLUSIONS: RECONNECTING RELEVANCE AND RIGOUR

The aim of this paper was to highlight some of the issues involved in producing both relevant and rigorous research within construction management, and to show that this simple opposition of academic and industry worlds, approaches and epistemologies neither fully captures the complexities of the issue, nor provides any headway into resolving it. There are numerous related challenges and sets of inconsistent demands. Research funders want industry-engaged, problem-solving research on the one hand and publications in quality journals on the other. Industry seems to want easy, directly applicable solutions. Universities want quality dissemination of corpus knowledge through teaching and cutting edge research which both addresses industry problems (and has commercial application) and maintains academic reputation. These statements are, of course, themselves oversimplifications; firms do not necessarily know what they want, or understand fully the problems they face. Research funders select and change priorities and funding systems in attempts to resonate with industry and government. Universities undertake a wide range of research activities, pure and applied, practical and abstract.

In short, the debate over relevance and rigour is not straightforward. Simple dichotomization of the two, although prevalent in many discussions, masks the reflexive and recursive interactions between bodies of existing practitioner and academic knowledge, cutting edge research and emerging problems within the landscapes of both industry and academia. It also hides some important questions about the role of academic research in supporting industry and its positioning alongside other forms of enquiry.

One firm conclusion is that leaping these hurdles involves challenging as well as accommodating business expectations and requires a process of mutual realignment (not just academic accommodation), as well as recognition at the level of research funding that the call for increased relevance is not a simple one. Such an approach reaffirms the importance of producing academic insights which are relevant partly because they are not constrained by the immediate pressures of business. This is especially important considering that the priorities of firms are not always in harmony with wider society. The burgeoning field of corporate ethical and social responsibility is one such area where the continuous pursuit of increased competitiveness is criticized, especially in the context of environmentally unsustainable business practices.

Debates about the nature of useful knowledge typically point to significant discrepancies between business and academia. Conventions, expectations and interests are not necessarily commensurable. Although there is a perceived need to reconfigure existing modes of collaboration, wholesale transformations, for instance from Mode 1 to Mode 2 knowledge production, are neither universally desirable nor likely to occur. This is especially true given the intransigence of existing academic practices centred around peer review and practitioners' equally firm focus on immediate problems and the pursuit of conveniently packaged 'solutions'. This is also reflected in the large market for consultancy.

At the heart of the issue of relevance and rigour must lie the understanding that in practice, business and academia reflexively interact with and influence each other. Academic terminology enters business vocabulary and in turn frames the actions of practitioners, even if those actions transform 'original' meanings. For example, how often is the concept of 'culture' or of a 'culture clash' evinced by practitioners as a means of understanding conflict? This connection resonates particularly with construction management – an area which borrows conceptual tools and methods from elsewhere and requires a willing, if not actively collaborating industry as its laboratory. CM research cannot escape its connections to both academic and industrial arenas. It is through the explication and exploring of these that its relevance and rigour will be revealed.

HAVE THE ECONOMICS OF CONSTRUCTION GOT CLOSER TO BECOMING A RECOGNIZED SUB-DISCIPLINE OF ECONOMICS? CAN IT DO SO?

Graham Ive[1] and Chen-Yu Chang

Bartlett School of Construction and Project Management, University College London, Wates House, 22 Gordon Street, London, WCH1 0QB,UK

The degree of progress towards recognition of a field of academic activity as a sub-discipline can be measured by three kinds of flow: (1) systematic citation of theoretical work in the main discipline by authors writing in the literature of the putative sub-discipline; (2) some citation, in the literature of the main discipline, of sub-discipline studies applying main discipline theories to the practical field of specialization of the sub-discipline; and (3) some overlapping of authors, with some authors writing sometimes in the journals of the sub-discipline and sometimes in the main literature of the discipline or the parallel literatures of other, recognized, sub-disciplines. Papers published in *Construction Management and Economics* between 2000 and 2006 are examined. Papers meeting criterion (1) are classed as 'economics of construction', other papers as either construction management or 'building economics'. The papers classed as 'economics of construction' are analysed in terms of the *Journal of Economic Literature* classification system. Some findings are presented regarding the size of all three kinds of flow, and conclusions drawn.

Keywords: economic history, economic theory.

INTRODUCTION

In 1994, George Ofori distinguished between ‘construction industry economics’ (related to the application of economic theory to the study of the construction industry, its markets and firms) and ‘construction project economics’ (relating to cost planning, life cycle costing and value engineering) (Ofori 1994). Myers (2003) noted that the introductory cover of the journal *Construction Management and Economics* states that: “construction economics includes: design economics, cost planning, estimating and cost control, the economic functioning of firms within the construction sector, and the relationship of the sector to national and international economies.”

Ofori concluded that “construction economics cannot be described as a bona fide academic discipline. It lacks a clear indication of its main concerns and contents and a coherent theory. It is not recognized as a distinct part of general economics” (Ofori 1994: 304).

The purpose of this paper is to re-examine the history and condition of construction economics from the perspective of 2007 – in particular, whether the recent evidence still leads its reviewer to Ofori’s conclusion. If not, what are the signs of an emerging sub-discipline here? If so, what (if anything) can or should be done to change that?

THE INSTITUTIONAL SETTING FOR CONSTRUCTION ECONOMICS

Who might wish to achieve such an outcome of recognition, and why? For anyone wishing to specialize in the study of construction from within the institutional support system of economics (that is, university departments of economics, economics research council funding) it is an obvious necessity. However, as James Buchanan (1969) pointed out, not all practitioners of 'the economics of X' are in fact dependent on such support systems. Buchanan had in mind agricultural economics:

> "Within a single (economics) department, fields or areas of…specialization may be added, dropped, transformed…Agricultural economics is however different precisely because in most universities it is organised independently as a self contained departmental unit, often…in a wholly different school from that which houses…economics" (Buchanan 1969: 1028).

Building economics and engineering economics have shared this difference. Today, many emergent specialist 'economics of' s are likewise housed outside of economics departments – for example, in institutes of transport studies (transport economics) or of health studies (health economics), and may draw funding from engineering or medical research funding bodies. (For example, the website of the Institute for Transport Studies at the University of Leeds explains that its 'Economics and Behavioural Modelling Group' employs "some 17 transport economists working in the areas of: efficiency analysis, econometrics, competition economics, charging and pricing and project appraisal, … (its) research sponsored by Network Rail, Department for Transport, Office for Rail Regulation, the European Commission and UK research councils" (www.its.leeds.ac.uk/research/groups/ebmg-transeconomics.php).)

University departments of the built environment (bringing together some or all of the professional education of architects, surveyors, building engineers, builders, construction and project managers, undertaking research studies of built environment issues from either one of a range of disciplines or from an interdisciplinary perspective) mostly date back to the 1960s and 1970s in Britain, and certainly no further elsewhere.

'Building economics' as a way of earning a living is for practical purposes an outcome of the existence of such departments. 'Engineering economics' has a separate if partly parallel history within faculties of engineering and, more specifically for present purposes, within departments of civil and mechanical engineering.

In the USA, Stanford University's Construction Institute, within its Department of Civil Engineering, was formed in the 1960s. The ASCE divided its Proceedings into the journals of separate 'divisions', of which construction was one, in 1963.

ECONOMICS-AS-SOCIAL SCIENCE AND DECISION-ECONOMICS

Economics can be divided into a part that is social science, concerned with understanding and explaining human behaviour and institutions, and a part that is 'decision theory' – mathematics applied to permit more rational decision solutions to complex choice problems (Buchanan 1969).

On decision theory, to cite just one paper out of very many, Fishburn (1991) sees the history of microeconomics chiefly as a move from classical decision making under certainty to new theories of decision under risk and uncertainty. For Fishburn, and for the vast majority of economists, this work is ‘theoretical’ because it is concerned with the axiomatization of models of behaviour used, whilst experimental work on decision behaviour is pushing economists to redefine ‘rationality’ (for example, definitions in which utility is not necessarily either independent or transitive) (Tversky 1969; Tversky and Kahneman 1986; Machina 1982; Sonnenschein 1971).

But ‘decision economics’ pushes across the boundary of economics into management science. At the margin, the problem in deciding what is ‘economics’ and what is ‘management science’ is where to draw a line within the body of ‘management science’, between that part that is derived ultimately from economic theories of behaviour, use of mathematical and quantitative economic methods, and the drive towards formal modelling, and that part that has other sources.

We will therefore distinguish two kinds of economics, to which construction economics may or may not have a close relationship: ‘decision economics’ and ‘social-science economics’.

In construction economics, however, there is little evidence (with the partial exception of bidding strategies) that our mathematical decision techniques are actually in widespread use by the actors whose behaviour as economist / social scientist we are trying to understand, and therefore OR-type work has not (yet) in itself turned construction economics into a recognized sub-discipline of economics.

We propose to make the ‘decision economics of building’ as a term extend to cover not only classic OR applications to bidding strategy but also client multi-attribute choice problems, such as contractor and procurement route selection, and applications of options valuation techniques to real options within construction projects.

Were construction economics ever to generate by its own breakthrough work on, say, the valuation of real options, the kind of practical impact that finance theory has had on financial options then, like finance, it would no doubt find itself being assimilated and welcomed into the fold of economics,. We will explain why we think such a breakthrough-effect is unlikely in this case in the last section of this paper.

Until such time, the best that construction economics can aspire to, in terms of recognition, is that it may develop by applying propositions, taken from economics-as-social-science, to the understanding of behaviour and explanation of institutions within the world of construction.

CONDITIONS FOR THE ESTABLISHMENT OF A NEW SUB-DISCIPLINE

Insofar as economics is a vibrant source of ideas – some of which have the potential to illuminate the world of construction activity – and insofar as that world offers an interesting and distinctive field in which to apply and test some of those ideas, then presumably it would indeed be desirable in itself, though perhaps not without its opportunity cost, for there to be a recognized sub-discipline of economics. But, and here is the focus, how far is it from being achieved?

A sub-discipline of economics to exist and continue needs:

1. To achieve a dual recognition: *both* recognition of expertise of its specialists in either a limited field of human activity (an ‘industry’, as it might be, agriculture, transport, health care) or in a dimension or attribute of all activity (as it might be, an aspect of the spatial or the historical); *and* recognition of a distinctively ‘economic’ (discipline-based) approach to that subject matter – thus not ‘transport studies’ but the ‘economics of transport’, etc.; not urban studies but urban economics. (Frenzel and McCready 1979).
2. To meet a demand.
3. To attract resources and develop capacity.

It has been proposed that as an emergent sub-discipline reaches towards the stage of ‘professionalization’, it will show most of the following (Davis 2002):

1. Specialty journals.
2. Organization of associations and societies.
3. Regular scholarly association meetings both apart from and in conjunction with general economics meetings.
4. Inclusion of the field in scholarly classification systems (e.g. the *Journal of Economic Literature, Social Science Citation Index*).
5. University instruction and doctoral supervision dedicated expressly to the field.
6. Ability of individual academics to credential themselves for careers within universities by work done in the field.
7. Book publishing opportunities with major publishers for scholars in the field.
8. Identification of special library collections.
9. Newsletters, bulletins, electronic lists.

It is proposed in the present paper that a necessary but not sufficient condition for a body of academic activity to be a recognized sub-discipline of a wider discipline is that there be two-way traffic between them. The sub-discipline, if it is to be such, will draw theoretical and methodological ideas from the wider discipline, and some results from work in the sub-discipline will receive attention from some practitioners of the main discipline or of other parallel sub-disciplines.

This paper is limited to examining the flows of theory and its application, and in one direction only, and neglects matters of methodology, as suitable subject for a separate study.

If indeed there are flows of the kind described above then, as a minimum, it follows that at the least there will be:

1. A process of systematic citation of theoretical work in the main discipline by authors writing in the putative sub-discipline.
2. Some reverse citation, most especially of the findings of studies applying main discipline theories to the practical field of activity that is the special interest of practitioners of the sub-discipline (sub-disciplines are often, in the social sciences, the nearest thing the pure theorists have to laboratories). Ideally, though this is more than a minimum requirement, some identification by the sub-discipline of phenomena paradoxical in terms of received theory.

3. Some overlapping of authors, so that some authors write sometimes within the journals and literature of the sub-discipline, and at other times within the 'main' literature of the parent discipline or the 'parallel' literatures of other sub-disciplines. This paper examines flow 1.

There are of course other conditions that must be met and other tests for the healthy existence of a sub-discipline. However, it seems to us plausible to propose that if these conditions of authorial relationship and cross-citation are not met, then the other conditions (such as: ability of the sub-discipline to attract young researchers trained in the parent discipline) are unlikely to be met.

We will therefore begin by imposing a distinction upon the kinds of work found in the literature of the putative sub-discipline: between works that do systematically cite theoretical work in economics, and those that do not.

In the empirical part of the paper, we will use the term 'building economics' (short for: 'building and engineering economics') for papers that: refer only or mainly to built environment literature, including other works of building economics or economics of construction, and not directly to economics literature. The influence of economic theory upon such work is not therefore necessarily absent, but it is at most indirect, mediated through the other works that are cited.

We will use the term 'economics of construction' for papers in construction management journals (specifically, CME) that, regardless of the manner of use or the outcomes achieved, do at least explicitly cite works of economic literature (either decision-economics or economics-as-social-science) as sources for their theoretical ideas and propositions.

Finally, we will use the term 'construction economics' as the overarching inclusive term for both 'building economics' and 'economics of construction'.

This distinction is not meant to be invidious, or to imply superiority in general of one kind of paper over the other. On the contrary, one can easily imagine several reasons why the achievements and qualities of the body of 'building economics' literature might be judged superior to those of its 'economics of construction' counterpart – certainly if judged from perspectives other than those of a theoretical economist. Nevertheless, to that economist, the literature of 'building economics' is unlikely to seem to be 'economics' at all – rather to be a field, perhaps like the academic study of accountancy, in which there is some overlapping with economics of language and concerns (For example, Bajari and Tadelis (2001), discussing the literature of procurement contracts in the RAND *Journal of Economics*, divide this sharply into the economic theory literature, exemplified by Laffont and Tirole (1993) and McAfee and McMillan (1988) and "by contract, the descriptive engineering and construction management literature" (in this category citing, *inter alia*, Ashley and Workman 1986; Finkel 1997; Hester *et al*. 1991; and Ibbs *et al*. 1986)).

A BRIEF HISTORY OF CONSTRUCTION ECONOMICS

The argument of this section is that the boundaries of construction economics have been set largely by changes in its institutional relationships to housing and property economics; and that, within those boundaries, developments of the agenda of construction economics have unevenly taken up opportunities opened by earlier developments in economics itself.

Stage 1 – up to the 1970s - no journal, no specialists

Before economic specialists in built environment departments existed, occasional economists made forays out from economics departments into the world of construction. Of these, Marion Bowley on innovation (1966) has perhaps had the most influence upon ‘construction economics’ in the UK, and Mills (1972) on labour and industrial relations in the US. Studies were mostly macroeconomic (see below) and work on costs and price formation (Andrews and Brunner 1975; Cassimatis 1969) stands out as exceptions.

Intellectually, in microeconomics the years from the 1930s to the1970s were the period between the fall of the ‘old institutionalism’ in economics and the rise of the new (Hodgson 1993). It has been argued by Hodgson that it was indeed the case that microeconomic theory then offered rather little to the would-be student of a particular industry and its firms, and that neoclassical economics was hostile to the very concept of an industry. (*The Journal of Industrial Economics* was founded and edited in the 1950s largely by economists sympathetic to the heterodox and, in orthodox neoclassical circles, hostilely received work of the ‘Oxford group’, such as PWS Andrews.) Nevertheless, to take two examples of influential early works of construction economics, the lack of reference to microeconomic theory in either Bowley (1966) or Turin (1975) is, in retrospect, striking. On the other hand, those early micro-economists of construction that did acknowledge theoretical debts tended towards the heterodox, taking their inspiration not from orthodox neo-classical microeconomics but from sources such as Shackle (Hillebrandt 1974).

Meanwhile, the 1950s were the key decade for the establishment of Operations Research (hereafter, OR) (the eponymous journal began in 1953, *Operational Research Quarterly* and the *Journal of the Operational Research Society* both in 1950). This marked the emergence of ‘decision theory and application’ as an important offshoot of economics. An early application to construction (bidding strategy) was by Friedman (1956).

Economics-of-construction studies of building cycles and the determinants of long term fluctuations in construction demand in advanced industrial economies (JEL E3) first flourished, largely as a series of monographs (Lewis 1965; Richardson and Aldcroft 1968; Burns 1935; Long 1940; Isard 1942a, 1942b; Kuznets 1930, 1958; Abramovitz 1961, 1968), then fell with the emergence of the view that such long building cycles (Kuznets cycles) and their drivers had become things of the past, suitable only for study by economic historians (Abramovitz 1968).

Another important early offshoot, not surprisingly given the then-salience of ‘development studies’ and ‘development economics’ (JEL O), was work on ‘the construction sector in economic development’. Of work published in economics journals, the paper most influential on the economics of construction was by Strassmann (1970), and the book with most influence that by Hirschman (1958). Hirschmanian linkages were taken up by Jones (1976) and Schultz (1976) – the latter published in Polenske and Skolka (eds.), a work on ‘Advances in Input-Output Analysis’, a topic soon to be the subject of a series of papers by Bon in economic journals (1977, 1984, 1986) (JEL O18, O41, D57, R15). This body of work was the product mainly of economists who were not (or not yet) located in built environment departments and who were economists rather than construction economists. Interest in these topics however fell with the fall in ‘development economics’ (Lal 1985; Krueger

1990) and in economic planning around fixed (Keynesian/neo-Ricardian) production technology proportions.

Stage 2 – from 1982-3 to the present – journals, and specialists

CME of course was founded in 1982, and the *Journal of the Construction Division of ASCE* was replaced by the *Journal of Construction Engineering and Management* in 1983. These events helped to separate construction economics from urban, property and housing economics, and to facilitate the decision-economics of construction by conjoining construction economics with construction management.

By the late 1970s, both regional and urban economics (JEL R) were booming, within which housing economics was emerging as a sub-discipline (R21 Housing Demand, and R31 Housing Supply and Markets). Housing economics was soon to occupy a large part of journals about space and products fixed in space, such as *Urban Studies, Housing Studies, Environment and Planning.* Departments of Land Economy, Real Estate, Planning and Urban Policy all grew, and often housed researchers working on housing and commercial property supply (and thus its development industries) as well as demand. It is in the late 1970s and early 1980s that 'real estate economics' and 'housing economics' become detached from 'construction economics' in the UK. The practical disadvantages of this split for the latter included loss of funding streams and rich markets for research and teaching. The intellectual disadvantages of the separation included an excessive separation of the economics of construction from the broader economics of the development process, including issues of land, user demand and financial assets (Bon 1989, 2001; Ive 2005). The compensating intellectual advantage was the resulting focus upon relationships between construction clients and their contractors.

This brings us then to the economics of the industrial organization (JEL L) of construction. In the 1970s, the 'old industrial economics' paradigm of structure-conduct-performance prevailed (Bain 1956, 1968). Within it, construction in advanced industrial economies was most obviously characterized by its low levels of national market concentration, and by being 'closed' to international competition.

The economics of organization was then transformed within a decade. Alchian and Demsetz's generally influential paper on the consequences of information costs came in 1972 and Williamson's book on the make-or-buy market or hierarchy paradigm in 1975. Soon came Klein *et al*. (1978) and Dahlman (1979). Eccles' two papers – much cited in the literature of the economics of construction – appeared in 1981 but the emerging transaction cost economics and economics of information was not taken up for construction until Reve and Levitt (1984), Stinchcombe (1985) and Winch (1989). It is notable that Eccles, Stinchcombe and Winch are all sociologists and not economists by original discipline, and became students of organizations from that route.

From the 1980s, onward fields began to emerge and gain recognition within economics that potentially bear closely upon the practical concerns of construction economics. These include: transactional relationships, contracts and reputation, networks (JEL L14), contracting-out and joint ventures (L24 and L33).

Meanwhile, the economics of auctions (JEL D44) received a stimulus. It is instructive to compare two early surveys by Engelbrecht-Wiggans (1980) and McAfee and McMillan (1987). The former appeared in *Management Science*, reviewed a bidding strategy (bidder decision) literature (some game-theoretic in method, some not) that had mostly (though by no means entirely) been published in OR or management science journals. The latter was able to report a new wave of interest by theoretical economists, and to answer the question “why study auctions?’ as follows (1987: 699-700):

> Some of the most exciting of the recent developments in microeconomic theory have been in the modelling of strategic behaviour under asymmetric information.

This is indeed economics-as-social-science, with a remit much broader than bid decision-support.

Important works of economics applied to construction written by non-specialist economists around 15–20 years ago include: Laffont and Tirole (1993), McAfee and McMillan (1986, 1988), and Dasgupta and Spulber (1989) on procurement auctions; Masten *et al*. (1991) and Lee and Png (1990) on temporal specificity; De Long and Summers (1991 and 1993) on investment and economic growth.

The ‘Findings’ section below will show the evidence (or lack of it) for the impact of these developments in economic theory upon the ‘economics of construction’ literature.

METHOD OF DATA COLLECTION AND ANALYSIS

The empirical scope of this study is confined to papers published in *CME,* between 2000 and 2006. This was by far the most prominent journal, in that period, to contain the words ‘construction’ or ‘building’ and the word ‘economics’ in its title. It therefore seems likely that here, if anywhere, is the first place to begin looking for evidence of a sub-discipline, on the criteria outlined in Section 4.

We reviewed the titles and keywords of all papers published in CME for signs or indications that the paper in question *might* be a work of the economics of construction, in the above sense, and *might* make reference to the literature of economic theory or to other recognized sub-disciplines of economics (excluding those of mathematical and quantitative methods, JEL C).

We took a ‘recognized sub-discipline of economics’ to mean one listed in the *Journal of Economic Literature* (JEL) classification system, D to R.

We then examined the references at the end of each ‘candidate’ paper, as follows. First, works not in English and all dissertations were removed because of practical difficulties in accurately classifying their discipline; as were (in part to minimize self-citation by authors, and in part because of difficulty of classification as economics) working papers and research reports except for those of a small number of institutions where we were confident that the discipline would be economics: for example, the World Bank, Bank of International Settlements, National Bureau of Economic Research. We removed references to basic (undergraduate) economics textbooks. We removed non-theory references to data sources, e.g. to yearbooks of statistics. We then removed all references published in building/construction journals, or books having construction or building in their title, unless their author was known also to publish in the recognized economic literature. The remaining journal papers and books were then each allocated to just one JEL class (sometimes with a cross-reference to other classes). Cited works were classed as ‘economics’ if either the journal in which they were published was one usually treated in libraries as an economics journal *or* if the title of the paper or book contained the word ‘economics’ (or a derivative thereof) or the words ‘theory’ or ‘model’ followed by a recognizable reference to an area of economic theory.

References to papers in OR or decision economics journals were distinguished from references to other economics.

At the junctions of construction economics with its ‘neighbours’ within economics, we have assumed those neighbours are themselves recognized sub-disciplines of economics – as for example with housing and property economics.

We next discarded purely methodological references (for the reasons explained above), for example to works on econometric techniques or time series modelling or statistics.

When in doubt we tried to err on the side of breadth in deciding what would count as a reference to a work of economics. For example, we treated Michael Porter’s many books as instances of application of the ideas of industrial economics rather than solely as works of management. We thus formed a ‘grey’ category of works cited that were neither unambiguously ‘in’ nor ‘out’ of the literature of economics.

If this left a minimum of five works unambiguously ‘in’, or eight or more that were either ‘in’ or ‘grey’, we considered the paper that had cited these works as being within the sub-set of *CME* papers qualifying for discussion here.

Evidently, there is an element of subjectivity in the procedures described above. If another pair of construction economists was to attempt to replicate the process of identification they might, at the margin, not exactly replicate our results. However, we are confident that such replication would not identify significant numbers of *CME* papers of ‘economics of construction’ that we missed, unless the researchers were to take issue with our boundaries between ‘theory’, ‘method’ and ‘OR’ literatures.

FINDINGS: THE BRANCHES OF ECONOMIC THEORY REPRESENTED IN *CME*

It is not clear whether or not there is a trend towards more ‘economics of construction’ in *CME*. On a generous definition (5+ refs to economic literature, as defined above), we count:

- 2006 = 15 papers (affected by special issue for Ranko Bon, to some extent).
- 2005 = 7 papers.
- 2004 = 15 papers.
- 2003 = 8 papers.
- 2002 = 12 papers.
- 2001 = 12 papers.
- 2000 = 4 papers.

Table 1: ‘Economics of construction’ papers in CME, 2000–2006

Economics of:	**2006**	**05**	**04**	**03**	**02**	**01**	**00**	**total**
Excluded (example):								
Price indices: time series modelling, regression, forecasting (tender price indices) (refs. to methods and works of building economics)			*1*		*1*	*1*	*1*	*4*

Included:								
Microeconomics (D)								
Transaction cost and property rights economics: total D23 (Organizational behaviour; transaction costs; property rights)	2		1		1	3	2	9
Transaction cost economics: [A] Boundaries of firm, make or buy, subcontracting	*2*		*1*			*1*	*1*	*5*
Transaction cost economics: [B] Transaction governance: inc. relational contracting *Could class also at L14 (Transactional relationships; contracts and reputation; networks)*					*1*	*2*		*3*
Property rights: [C]							*1*	*1*
Total Factor Productivity: production frontier functions; inefficiency; indirect measurement of TFP D24 (Production, cost, capital productivity, total factor productivity, capacity)	1		1	1				3
Market structure and pricing D4	1							1
Bidding (refs. mainly to operational research literature) D44 Auctions		1	1		2			4
Input-output analysis D57 (Input-output tables and analysis)	2	1		1				4
Macroeconomics (E)								
Building (and property) cycles and demand forecasting, and price expectations E3 (Prices, business fluctuations and cycles)		2			1	2		5
Capital stock, gross and net capital formation, depreciation, lifespan of capital, obsolescence E22 (Capital, investment, capacity)			1					1
E26 Informal economy; underground economy	1							1
International economics (F)								
Multinational firms in construction / international construction F23 (Multinational firms; international business)		1	1	2				4
Financial economics (G)								
Agency (incentive and information) problems: and application to corporate governance G3 (Corporate finance and governance)	1							1
Uncertainty and value of real options: total G13 (Contingent pricing; futures pricing) [also relates to D8 (Information, knowledge and uncertainty) and specifically to D81 (Criteria for decision making under risk and uncertainty)]	4		3		3	1		11
Uncertainty and value of real options: [A] to client / developer / owner, inc. BOT projects	*3*		*2*		*3*			*8*
Uncertainty and value of real options: [B] to contractor, inc. production resource allocation under uncertainty; pricing bids under resource cost uncertainty, with real options to switch technique and reschedule work	*1*		*1*			*1*		*3*
Labour economics (J)								
Labour productivity (LP): inc. direct measurement of output and labour input indices J24 (Human capital; skills; occupational choice; labour productivity)					1			1
J3 (Wages and labour costs); J31(Wage level and structure; wage differentials)			1					1
J4 (Particular labour markets); J41 (Labour contracts)			2					2
J6 (Mobility; unemployment; vacancies); J61 (Geographic labour mobility, migrant workers)						1		1

Industrial organization (L)								
‘Old’ industrial economics: Market structure, Competition, Concentration			1		1	2	1	5
L1 (Market structure, firm strategy and market performance)

5 JEL 3-diit (e.g. D23) ‘topics’ with 4 or more papers each (viz. D23; D44; D57; F23; G13)								31

Text not in parentheses is our description of the content of the papers allocated by us to that row.
Terms in parentheses are the names of JEL classes or sub-classes.
Text and numbers in italic are sub-sets of totals shown in other rows in bold.

Some 63 of the 73 papers fall into 10, admittedly sometimes broad, 2-digit JEL classes (JEL D to R contains 103 2-digit classes).

Table 1 and Appendix A show that of these 10 classes (63 papers), 7 (36 papers) represent pre-established fields within the earlier economics of construction that would be found in a similar analysis of the contents of *CME* in its first decade (bidding strategy; input-output; building cycles; multinational firms; market structure; firm performance, size and scope; economic development). (Mainly) new fields are: organizational behaviour/transaction costs/property rights; futures pricing/decision making under risk and uncertainty; and innovation (27 papers).

Areas of economic theory potentially relevant to construction economics and transformed in recent decades but not significantly reflected in the pages of *CME* include: applications of agency theory to incentive and information problems (only

Chang *et al*.2006); public choice theory; contract theory; intertemporal firm choice; information and market efficiency; corporate financing policy; procurement theory; compensation packages / payment methods; information and product quality; environmental and ecological economics.

Decision economics in *CME*

Most papers on bidding published in *CME* draw on other papers in construction economics and OR literatures, not on modern economic theory of auctions or procurement. The construction economics and OR literatures on bidding are particularly close, with the same authors often contributing to both.

The new literature on valuing real options is also a form of 'decision economics' and intersects with the OR literature (certainly real options papers sometimes cite papers in OR journals).

If we were to take bidding strategy and real options valuation together, and call them both 'decision economics', then together these would account for by far the greatest single slice of economics-based papers published in *CME* (4 + 11 = 15 papers), but a relatively small total compared to all 'economics-as-social-science' papers.

Gates (1967), Park (1966) and Friedman (1956) are much-cited classics of the CME bidding literature. The classic paper by Black and Scholes (1973) is cited in almost every CME real options paper. Books by Trigeorgis (1995; Brennan and Trigeorgis, 2000) are also much cited on real options.

Economics-as-social-science in *CME*

Occasionally, economics-based papers appear in *CME*, which seem at present refugees from their natural homes elsewhere. Examples would be Wong *et al*. (2005) and Hsieh (2005), both of which would belong in a journal of property / real estate or housing economics; and Johnstone (2004), which would belong in a journal such as *Environment and Planning* or *Housing Economics*. Duncan, Philips and Prus (2006) is in *CME*, it would seem, because the application is to building projects, though other papers by the authors are in journals of labour economics – their key concern is with wage regulation and its effects. A future increase in the number of such papers would have interesting implications for recognition of the journal within economics.

The most-cited 'economics' authors in *CME* 'economics of construction' papers include: Porter, Dunning (neither of whom publishes much in purely 'economics' journals), Casson, Williamson, Coase, Foss, Nelson and Winter. There does seem to be a substantial time lag before mainstream journal papers start to be regularly cited in CME.

In addition to our analysis of the contents of *CME*, we looked for signs of 'reporting back' to the broader economics community, in papers by construction economists in mainstream journals. Only a very small number of authors published both in CME and in recognized economic journals, in the period 2000–6.

Construction management and construction economics in CME

By analysis of their references, papers in *CME* in principle can be broken down into: 'management of construction' (by analogy with 'economics of construction', papers drawing on management theory or other management sub-disciplines), 'building management' (by analogy with 'building economics', drawing on other construction-specific management literature), ‘economics of construction’, and ‘building economics’.

However, whilst a proportion of *CME* papers draw overwhelmingly on just one of these four source areas, most draw upon two or more. This diversity and indeed inter-disciplinarity (across management science and economics disciplines) is characteristic of the journal, and is perhaps its greatest strength.

Building economics in *CME*

There are topics where building economics has developed a substantial body of cross- (self-) referencing literature, within *CME* and outside of it: for example, tender price indices (forecasting), or the evidence for and implications of ‘Bon curves’.

Most common publications for references cited in ‘building economics’ papers were ASCE journals, CIB proceedings, *CME* itself, BRI, ECAM, IJPM, ARCOM proceedings, Habitat International.

CONCLUSION

We found *CME* to contain little ‘pure economics of construction’, that is, papers with theory references solely to economics literature, but to contain more papers at the interface between economics and management, as measured by roughly equal citation of each type of source of ideas (e.g. boundary of the firm literature).

It seems therefore that we can conclude that the economics of construction is still closer to ‘management of construction’ than will be most economics papers to any body of management literature and that ideas coming out of economics do not predominate in it relative to those coming out of management science.

We also found a substantial body of papers that we categorized as ‘building economics’, because of their lack of reference to recognized economics.

Partly at issue in the assessment of ‘building economics’ relative to the ‘economics of construction’ is the extent of ‘uniqueness’ of construction. Certainly, it is specific. But there are two views – in one, it is so specific that it can hope to take little from a general literature developed with any and all industries or economic activities in view; its community of students must therefore learn collectively to be self-reliant. On the other view, if economics operates at too high a level of generality to be applicable, that is either the fault of mainstream economists developing ‘the wrong kind of economics’, or the fault of construction economists for failing in their task of adaptation.

The economics of construction should ‘ideally’ face two ways: back towards the sources of its ideas (which should include the economics profession), to whom it can report on applications of theory, and forward towards the users of its normative work, to whom it can make recommendations. Meanwhile it also needs to look ‘sideways’ at itself, developing positive analysis whose value lies in adding to our understanding of why construction is organized as it is – something of critical importance for the development of CE, but which is not perhaps a main concern either to mainstream economists or to construction ‘users’.

Since our analysis utilized publications in *CME*, it is perhaps apposite to conclude with some reflections on the impact of the existence of that journal on construction economics. There are aspects of quantity as well as quality to the matter of attracting attention. If the works we have labelled as ‘economics of construction’ that have appeared in *CME* (together with those in other construction management journals) were to appear on their own, not hidden in a broader body of diverse work, they might just be enough to sustain a slim quarterly journal. This journal would then be more visible as a place to look for papers on: the boundary of the firm in a project-based industry characterized by much subcontracting, on governance structures for long-lived and uncertain transactions, on I-O analysis for capital goods industries, on real options in investment projects, on international corporations in fields where literal exportation of products is not feasible, etc (i.e. topics broader than construction, but for which construction provides an important instance and source of evidence). But what would then be lost is that the built environment professional community, and the broader building research community might pay this work less attention than it currently gets by appearing in 'broad' journals like *CME*.

It is also doubtful that the set of topics listed in the previous paragraph have enough coherence as a set to sustain a separate journal. One has only to imagine what that journal might be called? The 'Journal of economics of projects and project-based industries' might satisfy some contributors, but not all – and would encounter resistance for encroachment on the preserves of others.

Usefulness is often, though not invariably, the precursor of recognition for a sub-discipline. Construction economics' relationships to a body of non-academic users will not be revealed by analysis of references. However, the challenges listed in Lander and Pinches (1998) to the practical implementation of real option models and valuation methods would seem to apply *a fortiori* to the decision economics of building. The assumptions we require for modelling are all too often violated in practical application, and our models neither well known to, nor understood by, the relevant body of practitioners. The small size and relatively unsophisticated nature of most construction firms, the heterogeneity of the decisions, and the occasional nature of most construction clients, combine to form an inauspicious 'demand side'.

Finally, the 'national' salience of the economics of construction would seem to be not unrelated to the share and role of construction in an economy. It is surely no co-incidence that the authorship profile of economic papers in *CME* now contains so many Chinese names. The combination of UK-influenced academic and professional institutions with East Asian shares of construction in GDP appears to offer particularly favourable circumstances (Hong Kong, Singapore, Malaysia).

BACKWARD AND FORWARD LINKAGES OF THE CONSTRUCTION SECTOR: AN INPUT–OUTPUT ANALYSIS AND THE BON CURVE IN THE CASE OF NORTH CYPRUS

Ozay Mehmet[1] and Vedat Yorucu

Department of Economics, Eastern Mediterranean University, Salamis Road, Famagusta, Cyprus

Relevant literature, especially the Bon curve, is used to document the dynamo role of the construction sector in North Cyprus on the basis of an empirical estimation of backward and forward linkages during the period 1998 and 2005. This was a period when the North Cyprus economy experienced an economic boom in the aftermath of the UN Peace Plan known as the Annan Plan for settling the Cyprus problem. The latest input–output table for the North Cyprus economy is 1998 and the authors had to derive backward and forward linkages for 2005 from a detailed breakdown of inter-industry transactions per unit of construction output using the most significant purchases and deliveries, normalizing these transactions for comparability between 2005 and 1998. The results reflect radically different patterns of inter-industry transactions in 2005 compared to 1998. The paper also has general interest in highlighting the possibility of a modified Bon curve for micro-states, such as North Cyprus, in which environmental constraints may be encountered earlier implying an inverted V-shaped Bon curve in place of a inverted U-shaped.

Keywords: backward linkage, developing country, environmental impact, forward linkage, input–output analysis.

INTRODUCTION

North Cyprus is a micro-state in the Mediterranean with a population of 256 644 (2006 Census) inhabitants and 3298km square land. Total GNP in 2005 was US$2327.8 million and per capita income was US$10 567 (State Planning Organization 2007). Input–output analysis is used to study empirically the explosive construction boom in the micro-state of North Cyprus. In 2006 the construction sector grew by over 35.2%, far in excess of the real GDP growth of over 13.5%, an explosive economic growth now in its third year. As explained in an earlier paper this boom is primarily triggered by the Annan Plan (2004) Referendum in May 2004 (Yorucu and Keles 2007) which aimed at ending political division in Cyprus. The implications of the Annan Plan for the construction sector have been discussed in a previous paper (Yorucu and Keles 2007). In a sense, this study is a sequel to the earlier one.

[1] ozay.mehmet@emu.edu.tr

The Bon curve presumes a two-stage secular relationship between construction volume and GDP which, in fact, is better broken down into three stages. In the first and early stage of economic development, a stage which may be called drive to maturity in line with Rostow's theory (Rostow 1956), construction growth exceeds the GDP growth rate and a steep positively sloped curve is reflected. In the second stage, both the GDP and construction reveal slower growth as the economy approaches a peak or 'maturity' stage. In the third and final stage, beyond maturity, the contribution of construction to GDP declines as other sources of growth (e.g. service oriented) emerge and overtake construction.

Although the existence of the Bon curve can be assumed generally, its shape is not yet settled. The exact nature of the construction–GDP relationship is a matter of empirical evidence and several questions of theory emerge over stages and transformations, over and above problems of statistics, sources and methodology. Thus, some question the slope of the Bon curve during the drive to, and beyond, the maturity stage. Thus, as economies 'mature', construction activity slows down and the declining portion of the Bon curve becomes flatter, indicating a declining importance of the construction sector in the economy. (This observed slowdown may also be due to the omission in official statistics of such construction innovations as fire alarms, security and internet installations.) Pietroforte and Gregori (2006), using Danish data, have verified this 'slowing down' of construction since the mid-1970s. Su *et al.* (2003), using data over 1964–99, have similarly found that Taiwanese construction, after rapid growth since 1969, declined after 1981.

The Bon curve also raises desegregation issues. Within the aggregate relationship revealed by the Bon curve, there are important transformations because the construction sector is a diverse sector, consisting of residential, institutional, commercial, industrial and other sub-divisions. During the course of economic development, the relative significance of these construction sub-sectors is altered in tandem with the Colin–Clark hypothesis (Mehmet 1999: 96) that with a rising GDP, the structure of the economy changes from being agrarian to industrial and then to service-based economic activity. Pietroforte and Tangerini (1999), using disaggregated Italian data for the 50 largest firms, have demonstrated that during 1980s and 1990s these firms have responded to changing industrial policy to adopt a service orientation in construction activity in order to remain competitive.

In micro-states, where the land constraint is encountered earlier compared to large economies, the drive to maturity appears to entail a shorter timeframe. This evidence confirms the Bon curve, but it suggests that the shape of the curve may be more like an inverted V rather than a U-curve. In order to escape the limiting land factor, micro-state construction has developed some innovative solutions such as vertical construction or going transnational. In the case of Singapore a 'transnational construction' specialization has developed (Cuervo and Pheng 2003), providing specialized and innovative construction services beyond Singapore's own boundaries, in nearby ASEAN neighbouring countries and beyond. Singapore's land constraint has also been partially overcome by means of an international 'growth triangle', whereby surplus capital has been utilized to acquire land from neighbouring Malaysia and Indonesia for development of huge industrial estates and export processing zones.

In Hong Kong, construction has gone 'vertical' with the majority of buildings coming into the 'multi-storey category' (Picken and Ilozor 2003). A further characteristic of Hong Kong construction is the role of expectations in price volatility, partly caused by financial factors and partly political linked to Hong Kong–Chinese relations (Wong *et al*. 2005). Political factors, specifically the Iraqi invasion under Saddam have also been a dominant factor behind construction in the oil-rich state of Kuwait.

FORWARD AND BACKWARD LINKAGES, 1998–2005

This part of the research documents the explosive construction growth in North Cyprus against the macroeconomic climate of the country.

According to the State Planning Organization (2005) construction growth expansion is strictly post-2002. The date is important because it reflects the onset of macroeconomic stability in reform when strict IMF-inspired reforms suddenly and significantly reduced inflation and interest rates and stabilized the value of the Turkish Lira. The results in North Cyprus of these macroeconomic reforms were immediate and laid the basis for a huge construction take-off after 2002. In the pre-reform period 1997–2001, the GNP in constant prices was virtually stagnant, growing merely at an average of 1.8%, in fact actually declining in 2000 and 2001. During 2002–06, the GNP growth rate jumped to an average of 11% per annum.

Construction played a key role in this economic transformation. Prior to economic reforms in Turkey, in 1997, the construction sector accounted for 8.1% of the GNP; 10 years later in 2006, this share jumped to 12%, becoming the second largest sector after trade/tourism, which includes wholesale and retail trade and hotels and restaurants. The construction growth rate, which during 1997–2001 was a mere 1.9% per annum, exploded to an average growth of 21.2% during 2002–06.

BACKWARD LINKAGES

Backward linkages in this paper relate to direct input interdependence between the construction sector and other sectors. Put differently, they refer to purchases by the construction sector of intermediate goods in inter-industry transactions. These input purchases, priced at producer prices, are the fixed coefficients indicating required amounts per unit of construction output.

In 1998, when the construction sector was stagnating as did the entire North Cyprus economy, the principal source of intermediate inputs for the construction sector was sub-sector 5 (manufacture of cement, lime and plaster-related articles) with 0.218 coefficient value, followed by sub-sectors 6 (manufacture of basic precious and non-ferrous metals) and 7 (wholesale and retail trade, sale, maintenance and repair of motor vehicles) with the second (0.142) and third (0.193) highest coefficients.

Table 1: Backward linkage coefficients, 1998 and 2005 (State Planning Office 2005)

Sub-sectors		1998 Coefficients*	2005 Coefficients*
1	Quarrying of stone, sand and clay	0.106	0.017
2	Manufacture of wood and products of wood and cork	0.043	0.137

3	Manufacture of other chemical products	0.042	0.015
4	Manufacture of ceramic products, cutting & finishing of stone & man	0.078	0.022
5	Manufacture of cement, lime and plaster-related articles	0.218	0.214
6	Manufacture of basic precious and non-ferrous metals	0.193	0.079
7	Wholesale and retail trade, sale, maintenance and repair of motor vehicles	0.142	0.182
8	Financial intermediation, except insurance and personal banking	0.055	0.331
9	Others	0.123	0.003
	Total inputs (billions of TL)	18.085	943.675
	Final demand (billions of TL)	13.565	2126.7
	Total construction output (billions of TL)	31.65	3070.3

Notes:
Values in producer prices.
*Formula: Sub-sectoral value divided by total construction output less final demand.

In 2005, sub-sector 7, the source of investment funds became the leading provider of inputs for the construction sector while the cement and related sub-sector 5 dropped to second rank with 0.214 coefficient value. The wholesale and retail trades, involving motor vehicles, kept their third rank (0.182), while the wood products sub-sector 2 moved up from eighth (0.043) to fourth (0.137) rank.

There were significant changes in the coefficients themselves. Thus, whereas in 1998 one unit of output required just 0.055 units of input from the financial sub-sector, in 2005, this coefficient rose to 0.33; in other words, the production of construction output in North Cyprus became significantly driven by availability of finance. Equally significantly, construction output became more than three times more wood intensive; the use of wood inputs per unit of construction output rose from 0.043 to 0.137. On the other hand, if we take the sub-sector as an indication of capital intensity, there was hardly any progress, presumably a reflection of the availability of cheap wage labour imports from Turkey. We were unable to calculate the import of primary labour input due to lack of necessary input–output breakdown. However, it is an observable fact that North Cyprus construction is heavily dependent on cheap wage labour imports from the Turkish mainland.

FORWARD LINKAGES

Similar to backward linkages, forward linkages relate to deliveries of construction outputs to other sectors, as intermediate goods, plus final demand components. The forward linkage coefficients represent how much the construction sector delivers to other producers and final demand users per unit of output.

Table 2: Forward linkage coefficients, 1998 and 2005 (State Planning Office 2005)

Sub-sectors		**1998 Coefficients***	**2005 Coefficients***
1	Wholesale and retail trades	0.056	0.458
2	Hotels and bungalows	0.512	0.207
3	Restaurants and bars	0.170	0.002
4	Construction	0.000	0.000

5	Financial intermediation	0.242	0.136
6	Other services	0.020	0.197
		1.100	
	Total inputs (billions of TL)	30.594	437.18
	Final demand (billions of TL)	31.694	506.44
	Total construction output (billions of TL)		943.62

Notes:
Values in producer prices.
*Formula: Sub-sectoral value divided by total construction output less final demand.

It will be observed from Table 2 that significant changes occurred during the explosive growth period under review. Whereas in 1998 hotels and bungalows (for alternative tourist accommodation) represented the top intermediate users of construction output (0.512), by 2005 this sub-sector was overtaken by the wholesale and retail trades (0.458). The third rank in 2005 belonged to other services, which are institutional types of users (0.197), e.g. hospitals, schools, which in 1998 were relatively insignificant (0.020).

One important aspect of construction in North Cyprus is the fact that outputs are primarily delivered for final demand users, intermediate users accounting for a much smaller share of total sector output. In 1998, no less than 96.5% of the total construction output went to final demand users. Although in 2005 this share dropped to 53.7%, which is a very large decline, final demand components were collectively still ahead of intermediate consumption. Within the final demand component, by 2005 private fixed capital formation was significantly outstripping the public share, in complete reversal of the position in 1998. In other words, by 2005, private sector demand became the driver of the construction sector activity.

ENVIRONMENTAL DEGRADATION

Explosive construction growth in North Cyprus has been largely unplanned and is now encountering environmental limits. As reported in Yorucu and Keles (2007), there is a fundamental conflict between private gain and public net benefit. A hot and highly profitable property market has attracted a large number of speculative investors and contractors pursuing private profit with no concern for the unique ecology of North Cyprus. In the process, the natural assets on the shoreline and mountains are being depleted, while infrastructural constraints are encountered with inadequate roads, electricity and water resources.

Government authorities have finally acted vigorously in 2007 in order to protect the public interest. Two actions have been taken. One is a sharp increase in the rates of property taxation. Since colonial times, property taxation in North Cyprus has been minimal and this has starved municipalities and local government authorities of much needed revenue to provide essential services and protect the environment. The problem has been well noted in a recent World Bank report (World Bank 2006) which recommended a significant increase in property tax rates. The Ministry of Finance has acted and introduced a threefold increase in property taxes to take immediate effect.

The other major policy action was the enactment of Cabinet decrees (TRNC Official Gazette 2006) putting a temporary ban on construction licences in the fragile Five Fingers Mountain Range in order to protect the watershed and the ecology of the area.

This is the latest amended Cabinet decree (TRNC Official Gazette 2007) for Kyrenia, supplementing earlier similar measures for Karpaz Peninsula in 2005 (TRNC Official Gazette 2005a) and for eastern (Tatlisu and Karpaz) and western Kyrenia (Akdeniz) coastal region in 2004–05 (TRNC Official Gazette 2004, 2005b and 2005c). These decrees have had the predictable negative impact on the construction sector. This means that the rate of growth of construction may not be at the 35% level observed last year, but it may fall to a rate that is much more sustainable in the long run. If demand continues for North Cyprus property at levels observed during the boom period, the impact of the Cabinet decree may be higher prices and better quality of construction as investors and property owners are obliged to pay greater attention to public interest in the protection of the environment.

CONCLUSION: A MODIFIED BON CURVE?

The ecological limit observed in North Cyprus has a significant implication for the shape of the Bon curve. It suggests that in micro-states with land constraint and access to cheap labour supply, the expansion portion of the Bon-curve may be steeper, the peak much more pronounced and the declining portion relatively flatter compared to the Bon curve. The steeper portion of the curve mirroring explosive construction growth in North Cyprus has been shown to be unsustainable and it is already being checked by tougher environmental and land zoning standards. The rate of decline in the downward portion of the curve is the function of political commitment in the implementation of the standards.

There is also an important theoretical implication emerging from our results. It is the suggestion that in the case of micro-states with a fragile ecosystem, such as North Cyprus, construction growth may be limited not by an inverted U, as predicted by the Bon curve, but rather by an inverted V. In other words, construction in micro-states may rise and decline at a much faster rate than in larger countries. In the case of Singapore and Hong Kong vertical construction growth may have a delaying impact, as noted in the literature. In the case of North Cyprus where vertical expansion is not an option, environmental limits are encountered much sooner and government authorities are then obliged to step in to protect net public benefit putting the brakes on explosive construction growth. Cabinet decrees discussed above are reflections of this limiting fact.

The inverted V hypothesis advanced here does not invalidate, but merely modifies, the Bon curve. It suggests that some sort of reconciliation between quantity and quality of construction activity occurs earlier in micro-states with fragile ecological assets, but, of course, the ‘lessons’ evident here have universal implications. What is suggested is that rapid construction growth has to be placed on a long-term sustainable footing to ensure that construction growth does not get out of control causing irreparable environmental degradation. The risks of such degradation being much higher in micro-states such as North Cyprus, the case for closer public scrutiny of construction activity is greater.

PROMOTING INNOVATIVE TECHNOLOGIES IN THE HOUSING SECTOR IN THE UK

Yamuna Kaluarachchi and Keith Jones

School of Architecture & Construction, University of Greenwich, Mansion Site, Bexley Road, Eltham, London SE9 2PQ, UK

The UK government has been advocating the implementation of innovative technologies to improve the sustainability of the built environment. It has the potential and strength in developing construction research in design and engineering, but the impact of these processes seems to be slow in reaching the residential sector. Given the large stock of existing dwellings, the situation is compounded, by issues related to climate change, to the point that this problem can no longer be ignored and requires an urgent response from all sectors involved. This paper attempts to highlight some of the key issues that are important in implementing innovative technologies in the housing sector. It briefly looks at the process of innovation in housing and presents lessons learnt from two research projects. The drivers and barriers and the role played by the government are examined in relation to the housing context. Economic benefits, improved performance, increased markets and organizations and their structure can promote innovation while funding, fear of risk, strict legislations, socio-cultural issues and mindsets of stakeholders can play a major role in hindering innovation in the residential sector.

Keywords: innovation, housing, sustainability, environmental technology, risk.

INTRODUCTION

The UK government has been advocating the employment of innovative technologies in the built environment for more than a decade. In its Sustainable Development Action Plan (Defra 2005), one of the key policy commitments is the “Implementation of actions arising from Climate Change Review” by Stern (2006). Stern states that the first essential element of climate change policy is carbon pricing, followed by technology policy, which is vital to bring forward the range of low-carbon and high-efficiency technologies that will be needed to make significant cuts in emissions. Policies to remove the barriers to behavioural change are stated as the third critical element. In addition, “research and development, demonstration and market support policies can all help to drive innovation and motivate a response by the private sector”. This timely review highlights the importance of incorporating innovative environmental technologies in all sectors and industries in reducing the impact of climate change.

Innovation in the current context has to incorporate issues of social, environmental and economic sustainability, where quality of life issues are given a high priority. Awareness of climate change and the adaptations of building stock have to play a key role in the environmental agenda. While some European countries and countries like Japan move forward by bringing their sustainability agenda to the public sector, the UK seems to be slow in embracing these ideas. A number of reviews of the construction industry provided waves of re-structuring and re-inventing, but long-term sustainability in improved products and processes for better performance, efficiency and innovative application of renewable and low carbon technology serving the built environment is yet to come. While funding remains a major constraint there are many other issues that directly or indirectly influence this process.

The UK has a fairly mature building stock which must be taken into account if a significant change in environmental performance is to be achieved. New buildings only add between 1–5 % of the total building stock each year (Wigginton *et al*. 2002). Intelligent application of advanced ‘smart’ facade technology in conjunction with innovative environmental systems can result in significant energy savings and – at the same time – improvement of indoor comfort. Kragh (2001) claims “It has been shown that, when designed carefully, innovative systems do not represent additional initial building costs. Running costs are lower and energy costs can be reduced by approximately 30% compared with conventional solutions”. The UK has strengths and further potential in developing construction research, design, engineering and project management, but the impact of these processes do not seem to be reaching a majority of players in the housing sector. The intention of this paper is to highlight some key issues that are important in implementing innovative technologies in the housing sector. It briefly looks at the process of innovation and its status in the housing context and presents lessons learnt from two research projects to illustrate factors that promote or hinder innovation. The discussion also examines the role played by the government in focusing attention on new opportunities for innovation, as well as on the barriers and constraints set by legislation. It is not within the remit of this paper to present the methodology, data and results of the research projects in detail, although some relevant findings are presented to illustrate and highlight some of the issues discussed.

THE INNOVATION PROCESS

The innovation process is defined by experts as “the successful exploitation of new ideas” (Dodgson *et al*. 2006), and which results in “enhanced performance and delivers objectively new or improved services to the user” (Seaden 2005). Recent authors have stated that “innovation is not a discreet or entity, but a socially mediated process that results from, and contributes to, a range of systemic relationships and interdependencies” and “from organizational, managerial and individual practices and decisions” (Dodgson *et al*. 2006). Their view of innovation is as a socially constructed and not technologically determined process, noting by way of introduction that “innovation is, and will remain, a socially determined and hence unpredictable process” and concluding that “technological change requires associated social, organizational and managerial changes”. There is also a consensus that innovation is risky, requires significant investment and is often resisted within firms (Seaden *et al*. 2003).

Innovation is often categorized according to whether it involves the development of a new product – by a new or established technique – or the introduction of new processes for producing an established product (Livesey 1983). While many people associate innovation with major technological or organizational advances, the vast majority of successful innovations result from a stream of small incremental changes that may individually have only limited effects on consumer behaviour (Foxall 1984). Organizational growth can also encourage innovation, as the number of product or service lines increases and existing products at various stages of their life cycle evolve. The consensus of an international Symposium on Construction Innovation in Ottawa was that innovation is becoming the principal tool to achieve greater market penetration and increased profitability, which was echoed by a study in Chile, where innovation is driven by increasing client's requirements, greater market competition and globalization (Serpell *et al*. 2001).

An ability to manage innovation as part of the overall corporate strategy is as important as the innovation itself. An organization's response to innovative ideas and its ability to transform them into viable products is influenced by its organizational structure and culture. These include a fear of change, or the disruptive impact of innovation on existing organizational hierarchies, work processes or management structures. Managing innovation essentially involves mediating between external forces for change and internal forces for stability. Innovation is rarely constrained within the boundaries of individual firms (Dodgson 1994). Firms learn both from their own experience of design, development, production and marketing and from a wide variety of external sources (Freeman 1991).

INNOVATION IN THE HOUSING INDUSTRY

Innovations in the built environment are often a complex blend of government, business, market and consumer decisions. In the housing sector, the homeowner or tenant is the ultimate user, but often is not involved in the decision, except through other agents (housing associations, builders and government) who purport to act in the future occupant's interest. Consumers also rely on the government for protection against failures in the system. Building material and process failures are extremely expensive to correct and can easily damage the financial position of consumers, as well as severely diminish their personal satisfaction with their homes. Given the problems facing building innovations (risk, invisibility, uncertainty, cost of failure and correction, 'trialability', and difficulty in establishing relative advantage in the short term) consumers probably expect government and building officials to be conservative in their acceptance of innovations. Reducing risk may be as important to homebuyers as cost savings. If so, time-honoured technologies and processes will not be abandoned without ample evidence that their replacements will perform as expected. This socio-cultural fear of change and risk is deep rooted, difficult to change and forms a major barrier in bringing innovation to the housing sector. Information sharing and responsive communications can contribute in combating these fears.

"The housing industry has long been recognized for its seeming resistance to change and is widely seen as being slow to produce or embrace technological innovations" (Koebel 1999). Market interventions promoting new construction date back to the immediate aftermath of World War II. Mass production techniques were promoted in Europe to overcome the enormous housing shortages left by the devastation of war. Public housing construction in the United States pursued similar technological fixes in producing low-cost housing. However, the results of those particular innovations were sterile environments that grew increasingly unproductive as occupancy demands shifted.

The main rationale for innovation in the housing industry is economic benefits related to cost reduction and quality improvements. Other rationales include tackling environmental and structural problems and achieving public policy objectives. The rationale for government support of innovation in the housing industry focuses on the social and economic importance of housing. It acknowledges the value of innovation and the social benefits to be obtained from improved industry performance and the need for government funding in order to offset the industry's characteristic underinvestment in innovation activities. As evident from the results in Case Study One, government support can be crucial for innovative projects to sustain their investment in a competitive housing market.

An environmentally sensitive and sustainable residential development requires houses that are more durable, energy efficient and less wasteful of land and material resources. These objectives cannot be achieved without advances in technology: “Sustaining sustainability requires innovation in technology, new materials, new products, and new processes, and adoption of innovation in building” (Koebel 1999). This process can be easily adopted in new construction, where technological advances can be introduced into the built environment at an early stage of the project. But the complex problem lies with the existing built environment. In the UK, the existing housing stock greatly exceeds the mass of the newly built dwellings. For a variety of reasons, retrofitting and renovating solutions are more complex than new-build ones, but these are unavoidable if sustainability challenges are to be met. Case Study examples from Research Project 2, Sustainable Urban Environments, illustrate that very little innovative environment technologies are implemented in the refurbishment of the existing housing stock. While initiatives such as the ‘Decent Homes Programme’ (DETR 2001) is intended to improve the environmental performance of dwellings, they sometimes achieve the opposite results, as housing authorities treat these schemes as vehicles for obtaining more funding rather than achieving sustainable dwellings. Research shows that when there are opportunities to employ new and innovative technologies in refurbishment, housing authorities implement basic or out-of-date technology to update their stock due to tight budgets and fear of risk (Green Street, Sustainable Homes 2003).

A number of authors (e.g. Gann 1996) have argued that some of the challenges in new-built housing could be met if house builders learnt lessons from the manufacturing industry, such as the construction of housing from a number of interchangeable component sub-assemblies. This type of approach would require a radical reorganization of the housing supply system, with component manufacturers and end-users playing a much larger role in the design process, and reorganized supply chains. Research Project 1: Monitoring Egan Compliance illustrates some crucial lessons learnt in such an initiative. Unless there is a high level of demand, the investors cannot sustain the initial capital costs required in factory-based production. The level of demand depends on many different criteria including cost, market forces, affordability and subsidies. In many cases, demand also depends on the degree of confidence in the product, the trust and the fear of taking risks by trying out new products and systems. The failure of large-scale change in homebuilding notwithstanding, technology innovations have been introduced and adopted within the industry. For example, manufactured housing now contributes a significant portion of total residential construction.

LESSONS FROM TWO RESEARCH PROJECTS

Project 1: monitoring an innovation programme to examine Egan compliance in social housing in the UK (2001–4)

Project 1 monitored a consortium of Register Social Landlords (RSLs) established to provide high-quality housing designed and procured in line with the principles set out in the Egan Agenda (1998). A strategic partnering arrangement was set up with a single contractor who developed an award-winning, modern, pre-fabricated timber frame housing system and built a customized factory production unit. It was an opportunity to monitor and record the performance of 28 housing development projects and the roles played by a complex team network in contributing to a strategic partnering agreement. As the RSLs agreed to procure 2000 new house units over a four year period (2001–5), a research project was set up to exploit this opportunity to study a major innovation programme and identify what key lessons could be learnt. The selected contractor was the subject of several takeover bids by rivals and experienced a number of problems with both, the supply of the timber frame housing system and site personnel, which compromised the quality of construction and resulted in a high turnover of site-based operatives. This, together with other problems (outlined below) meant that the volume of demand initially forecasted never materialized.

The main aim of the research was to set, monitor and compare the Key Performance Indicators (KPIs) and map the cause and effect relationships within the change programme. The details of the research methodology, data and analysis are beyond the realm of this paper and are to be published elsewhere (Kaluarachchi *et al*. 2007, under review). A brief summary is presented below.

Research methodology

The research methodology was based on case study monitoring and action research, developing a data collection and management of information system that could monitor the impact of the consortium's approach on the principles outlined in the Egan Agenda. Relevant KPIs, benchmarks and a data collection and site monitoring system were developed by the research team. A range of questionnaire surveys, detailed interviews with key project personnel, examination of site meeting notes and general feedback reviews were undertaken to identify good and bad practices associated with each project. An attempt was made to identify the softer, qualitative issues that are difficult to handle with normal numerical data collection methods.

Key lessons learnt from the initiative:

- All parties needed to be committed to the innovation programme. Failure to recognize the dynamics of the situation and, in particular, to deliver against the expectations of all parties, results in a breakdown of trust and confidence between partners.
- The level of demand required to sustain the contractor's performance should be ensured. In this instance, the contractor invested heavily at the inception of the project hoping to recover the capital costs as the projects progressed. The demand created did not justify the upfront investment and the market did not provide the opportunities that were expected. All the risk and loses had to be absorbed by the contractor. Risk management processes needed to be in place prior to commencing the project.
- Innovative procurement processes requires a change in mindset at all levels within the organizations. Effective mechanisms should be put in place to ensure that everyone understands the joint goals and know their part in the overall process. Training was identified as an essential ingredient in this process. The lack of familiarity with the innovative approach illustrated the need for formal training for all project managers, prior to commencement of new projects. There was also the need for support systems in terms of knowledge and information to be in place for frontline staff.

- Communication and co-ordination, which lead to continuous improvement of services and products, emerge as some of the key drivers for the successful delivery of quality social housing that meet both time and cost targets.
- Even though the government encourages initiatives, such as that monitored in the research study, there is little flexibility in support systems to assist in sustaining them.

Project 2: stakeholder consultation for sustainable urban environments project (SUE_IDCOP, 2004–7)

The SUE-IDCOP programme is responsible for providing the fundamental knowledge to underpin the improved sustainability of existing buildings. The overarching aim is to find ways to improve the performance of existing building envelopes that reduce the consumption of non-renewable resources over the whole building life cycle in a way that is economically viable and socially acceptable. Such facades could also provide performance data that could reduce the levels of waste associated with its maintenance and refurbishment. At the same time, energy and pollution would be minimized.

There are many innovative environment technologies that are readily available in the market. Case study examples here in the UK and extensively throughout Europe show that these technologies can be used effectively and economically in new build housing. In the UK, there is very little evidence of their use in routine maintenance and refurbishment. The UK construction industry, mainly the residential sector, seems to be cautious and slow in implementing these technologies. The current data on refurbishment illustrate that very basic building technology, sometimes unsustainable, is used to upgrade the dwellings.

As part of the ongoing research, two stakeholder consultations were undertaken. In this paper, only the results from these two consultations are presented.

Consultation 1: a pilot study of six major housing associations to identify barriers in promoting innovative environment technologies in refurbishment

The aim was to identify and review the barriers that stakeholders face in promoting innovative environment technologies in social housing refurbishment. The consultation was carried out in relation to three sectors in the procurement of social housing; management, development and the maintenance sector. It was considered under the following criteria: energy performance, water performance, waste management, durability and flexibility (whole life performance), and health and well-being of tenants (quality of life issues).

The results illustrated that:

- Value for money is a major governing factor. The benefits should outweigh the costs incurred. The RSLs work on a tight budget and unless it is proven that the benefits outweigh the capital cost, none of the new technologies are considered for implementation. The capital costs of most of these technologies are significantly higher than the available budgets and the potential cost savings in utility bills. The tangible benefits of employing renewable technologies are usually long-term and do not result in quick savings.
- The technology should be proven and fully demonstrated.
- There are quite a lot of products and systems in the market but very little information about their long-term performance, durability and ways in which

they can directly reduce cost. More information about whole life performance and cost savings is needed and should be made available to the RSLs.

- Confidence levels in the new products are low due to high costs in demonstration projects.
- Organizations are reluctant to take the risk.

Consultation 2: stakeholder engagement regarding sustainable refurbishment
A stakeholder consultation workshop conducted with 50 members of an RSL ready to embark on a sustainable refurbishment programme showed that current building technology applied in refurbishment of dwellings is basic. The group consisted of managers, technical officers and neighbourhood officers. Asked the question "What are the environmental technologies that can make a real difference in tenants' life?", 100% of the respondents listed double glazing and efficient heating as their first priority and insulation as second. This illustrates the problem that is faced by current stock in failing in thermal comfort. The responses are related to alleviating fuel poverty, which is a basic requirement rather than embark on a radical refurbishment of the existing stock to the current building standards. Implementation of renewable technology measures was stated by three groups at varying levels of priority, but not a criterion listed by the decision makers (managers) as important.

All participants agreed that the number one criterion that acts as the barrier in implementing these sustainable technologies is a purely financial one, "initial cost, value for money and long payback periods". By popular consensus, "tenants' attitude, lack of interest, fear and behaviour" came as the number two criterion. Three groups agreed that the 'structure of organization' also play a key role in this process and cited it as their number three barrier. A lack of maintenance staff, reluctance to take risks, politics and legislation were also cited as other barriers.

When presented with the question "Criteria that influence the decision making process in allocating resources", the managers' group came up with a list that they thought best illustrated the crucial criteria and stressed the fact that funding issues span and govern all the other criteria as a major issue. The main criteria tabulated were:

- Statutory requirements, achieving government targets, tenant interest requirements, good value for money (payback period, options), annual budget, speed of delivery and lease holder tribunals.

Justification of resources; issues pertaining to increasing rent to recover the capital costs and the constraints held by tenant tribunals in challenging each of the RSLs decisions regarding improvements to the housing stock, were also stated as deterring implementation of any innovative ideas.

DISCUSSION: FACTORS THAT AFFECT INNOVATION

Factors that affect the implementation of innovative technologies define the context in which the industry operates. The globalization of markets, increased environmental requirements, higher consumer expectations and increased competition are examples of such factors and normally lie beyond the control of these organizations. "Three sets of factors that affect innovation and are controllable constitute elements to develop strategies to foster more innovation in housing. They are referred to as innovation accelerators, innovation barriers and contingent factors (factors which can foster or impede innovation, depending on how they are managed or implemented)" (National Research Council of Canada 2002).

The first major reason for innovation is economic benefit. This can be reflected in various ways, such as increased profit, increased market share and business growth. Another reason for innovation is remedying problems that result in better performance and related economic benefits. Increased investment in research and development of products and services can facilitate innovation and better performance. A third reason for innovation is to achieve public policy objectives, such as energy conservation. The public policy rationale for energy conservation may well be environmental preservation; the private sector rationale may be reducing operating costs of homes or businesses and making profits by marketing improved products. The housing consortium monitored in research project 1, was set up to achieve a 'better performance at an affordable cost using factory production techniques' as was advocated in the Egan agenda.

Organizations and their structure have a major influence in the innovation process. Visionaries who have corporate influence can drive innovation and influence the market growth, but will need support from other organizations in stabilizing the process and creating the demand that is needed to establish the market. Developing a culture of innovation in organizations and industry appears to be vital in triggering innovation. The main driving forces are the ideas of stakeholders, i.e. customers, management, marketing personnel and production personnel, as they focus on problem fixing and developing new ideas. Project 1 was set up solely by a visionary who wanted to achieve real change in the social housing sector. But as the lessons from this experience show, the organizational structure and the support that was needed to facilitate such an initiative was not present. The commitment of all parties, a changed mindset at all levels and better communications between all levels were crucial requirements to make the initiative a success.

The housing industry has a serious shortage of skilled labour. A skilled workforce is critical to an organization's ability to innovate. Training and education are essential in the development of a skilled workforce. In Project 1, the contractor experienced many problems due to his inability to retain skilled workers. The lack of demand for the houses (mainly due to rival takeovers) slowed down the factory production and affected the retention of staff, which in turn affected the quality of the product. Poor quality products resulted in losing the trust and confidence of the consortium members and reduced the demand that was originally envisaged.

Research, development and increased patronage by the government and other funding agencies can drive innovation. International competitiveness and increased and improved access to domestic and international markets can also have a positive influence on innovation.

Risk is one of the main barriers to innovation. Innovators face many types of risk, including performance failure, market rejection, delayed or non-approval by regulatory authorities, rejection by trades/labour and liability. All of these risks have an associated potential financial loss, and the trend is towards increasing risk, particularly risk of liability. Results from the stakeholder consultations showed that many housing organizations are reluctant to implement innovative technologies due to fear of taking risks, and consider implementing only basic technology in their refurbishment programmes. A snapshot of case studies given in Green Street (Sustainable Homes 2003) illustrates the current status of refurbishment and the savings that can be achieved with the most basic environmental upgrades in the short term. In many examples (Case study Sandwell, Green Street), refurbishment costs about 15% higher than for comparable conventional housing are considered a worthwhile investment, due to the fact that maintenance costs are likely to be much lower than for traditional council homes.

Financing innovation has always been a key problem. Small and medium companies find it hard to invest in research and development and hence break into new markets due to financial constraints. Research Project 1 shows that, in some instances, there are considerable upfront capital costs, but increased consumer demand and a greater market share will contribute to recover these costs. In Project 2, the housing associations were reluctant to spend the initial capital cost required, without having guarantees that they will be recovered within a limited time. Usually in the housing sector, developers are also wary of implementing new technologies because of fears about consumer preferences. Consumer demand affects the supply and market investors and stock market analysts become concerned about investment in new techniques or products which may be regarded as risky. Project 1 showed that without sufficient demand, a new initiative could not sustain itself. Lack of consumer demand coupled with the inflexibility of building regulations and regulation administrators are commonly regarded as detrimental factors for innovation.

The housing industry is heavily regulated by national and local regulations governing land use and planning, infrastructure and buildings. Literature reviews, experiences from the housing industry and research indicate that regulations are a major barrier for innovation. In particular, factors such as lack of mandate to accommodate or foster innovation at the local level, and lack of empathy by local building officials to accommodate innovations, are detrimental to the process. It is the availability of incentives that promotes innovation. These incentives could be of various forms, such as tax or VAT refunds and targeted funding and support. Some incentives, such as compensation to offset costs of training trades on how to incorporate innovations, may also be useful.

The social systems surrounding housing production resist change. This could be due to inflexible mindsets, socio-cultural values, or simply fear of change or taking risks. In order to achieve the full benefit of innovative technology, the user has to be familiar with its use. Educating the occupier is crucial to overcome these setbacks. Research carried out by Sustainable Homes (2003) showed that, given the right information and control, tenants are happy to implement new environment technologies in their dwellings. Savings in utility bills can be a major incentive in this process.

The Government’s role

The government and public policy makers might desire green, sustainable buildings and affordable housing, but they have few clear tools to achieve these within the current market. Governments can enhance or slow innovation processes. Despite governments advocating innovation, there is very little support to sustain the growth of innovation. In the past, government interventions were typically in the form of more regulations, which too often impeded the very progress desired. Local government enforces building regulations and is in a position to prohibit or enable building innovations. Advocates for adoption of building innovations have to change building codes to enable builders and/or consumers to adopt any favoured innovation.

Current policy in the UK identifies the experienced client as the main institutional leader in stimulating construction innovation, yet doubts remain regarding a client’s ability to play this role. Nam and Tatum (1997) show that a client needs to be technically competent in order to understand innovative proposals from systems integrators, and hence take the risk of innovating. From this perspective, a particular weakness of the British system is that the single most important client – the state – has no equivalent competency to assess innovative proposals, while many local authorities, private sector clients and privatized utilities have been outsourcing their architectural and engineering functions. The analysis of complex systems industries also suggests that more attention needs to be given to the two other elements of the innovation superstructure: the regulatory environment on the one hand, and the professional bodies, research establishments and universities on the other. “It is the way in which the professional institutions carried out their brokering role that sometimes slowed the innovation process, and it was this brokering that provided the basis for the new regulations” (Winch 1998).

The UK Government is committed to expanding its supporting programme for renewable energy technologies including research, development, demonstration and dissemination. The main current hurdle preventing large-scale manufactures of photovoltaic panels in the UK is the current market, or lack of it. The understanding and potential of photovoltaic technology is improving, but further research and development is required to achieve cost reductions. It is important that strong partnerships are established between industry and government. Increasing environmental concerns and the need to achieve emission reduction targets should help the technology to become further established as a marketable and economically viable product.

Government incentives in terms of tax benefits and funding can facilitate the innovation process. Clear government targets and patronage can make the residential sector embrace innovative strategies into practice. New innovative procurement methods and contractual reforms have to be introduced to achieve the targets set. Initiatives such as Partnering (PPC 2000), Private Public Partnerships (PPP) and Private Finance Initiatives (PFI) contractual agreements were introduced as a result of Latham (1994)and Egan (1998) reviews. If the UK government is to meet its CO_2 reduction targets, many innovative technologies have to be incorporated to the existing building stock.

CONCLUSIONS

The housing sector is slow to embrace technological innovation. Housing authorities are reluctant to introduce or implement innovative environment technologies in their housing projects due to the initial extra capital costs, fear of taking risks and lack of demonstrable examples. Research shows that many factors need to be overcome to make this process viable. The housing associations must consider the whole-life cost savings, as a way of recovering the higher initial costs in the long-term, and persuade their tenants to this way of thinking rather than settle for quick-fix solutions that are outdated. Savings in utility bills can be a good incentive to try to accommodate some of these sustainable technologies in the dwellings. Information sharing, responsive communication, training and personal control can contribute in assisting the tenants to adapt to these new technologies and processes.

The drivers of innovation are economic benefits, performance improvements, environmental upgrading, research, development and information and knowledge transfer techniques and access to markets. Governments can play an important role in the innovation process. Support mechanisms in terms of resources, incentives, providing opportunities and access for local and international markets, training and information sharing mechanisms all can foster innovation.

While the implementation of innovative technologies can be accelerated with the right government-led incentives like subsidies, tax benefits, availability of resources and information, the removal of barriers will be equally if not more effective: less strict regulations or reduced financial risk. Risk is one of the main barriers to innovation. Organizations can control risk by researching innovative technologies to reduce the number of unknowns about them, establishing quality control measures to reduce product deficiencies and training staff to increase their competencies.

Finally, it should be noted that unless social, economic and environmental criteria are all addressed, there is no stability in innovating in the housing process. The ultimate aim of the industry is to produce housing, which provides greater comfort and improved energy efficiency with a higher level of amenity and aesthetics. It is also safe and more secure, using advanced systems and stronger construction techniques. In addition it is healthier through the use of better ventilation techniques and materials, which are more sensitive to the environment and make use of recycled materials and resource-efficient materials, and which provide an improved quality of life for the inhabitants.

A CONGESTION CHARGE FOR DUBLIN

Martin Rogers,[1] Cathal Eagney and Eamonn Maguire

Department of Civil and Structural Engineering, Dublin Institute of Technology, Dublin 1, Ireland

As Dublin becomes more congested, the option of imposing a charge for access to central Dublin at peak times has become a realistic one. This paper outlines, in brief, the history of Dublin transportation planning that has led to this point, lists the alternative number of demand management tools which potentially could be used to limit demand for private car travel to the city centre with the implementation of a congestion charge being an option which would be particularly applicable to Dublin city. The paper details other capital cities where such a charge has been implemented,, indicating in general terms the reasons for the charge and its level of effectiveness in reducing congestion. Estimates of the willingness of road users in Dublin to pay such a charge are put forward. The Dublin Transportation Office's Saturn Model is used to quantify the effect of different congestion charges on car usage into Dublin city centre at peak times. Effective implementation of such a measure is only seen as taking place within the context of improved public transport services within central Dublin.

Keywords: congestion, economics, transportation.

INTRODUCTION

Dublin is now a car city. In the centre of the Dublin City area, household car ownership is 58% and in South Dublin household car ownership is 84% with 41% having at least two cars. Dubliners use their cars to travel to work, to shop, or for leisure purposes. For most people, normal life without a car would be impossible. Dublin is car dependent.

Over-dependency on the car as a mode of travel leads inevitably to traffic congestion. Traffic congestion increases business costs, as moving people and goods around the city takes more time, commuters complain as traffic jams multiply, commuting distances and times grow longer. In addition, it is detrimental to the environment.

Previously in Dublin, transport planning was seen to primarily involve the implementation of the 'predict and supply' model, with the solution to congestion seen to involve the construction of yet more roads. The role of the transport planner was, primarily, to calculate the future levels of car ownership and to ensure that roads are built as quickly as possible to facilitate the classical predict and supply behaviour. However in the context of modern transport planning, this mindset is no longer acceptable. It has been proven that the construction of more roads merely leads to more cars and ultimately more traffic jams on Dublin roads. It has therefore become necessary to consider other measures aimed at reducing congestion in Ireland's capital city, including travel demand management measures.

TRAVEL DEMAND MEASUREMENT MEASURES

Travel demand measures are primarily demand rather than supply oriented. It is a process which attempts to manage people's travel as opposed to attempting to provide more capacity on the travel network.

Travel demand management therefore involves the putting in place of projects/measures which seek to alter the pattern of travel demand. Booz Allen Hamilton (2004) identified the following ways in which this could be achieved:

- Reduce vehicle use: bring about a reduction in car travel at peak times.
- Increase use of alternative modes of transport: introduce measures to encourage an increase in public transport usage.
- Increase vehicle occupancy: bring about a decrease in single occupancy car trips and encourage multiple-occupancy.
- Reduce trips: bring about a reduction in the need to travel.
- Reduce trip length: plan for the provision of places of employment and shopping outlets in close proximity to residential areas.
- Alter times of travel: encourage travel at off-peak times to lessen congestion.
- Propose alternative destinations for trip makers: encourage trips to destinations that are closer to their origin, along less congested routes.

In the context of Dublin, of the above list of potential measures, the first two were seen as being particularly applicable to the city, i.e. the putting in place of measures to discourage travel at peak times by private car, hand-in-hand with the implementation of infrastructure proposals and associated measures to deliver greater modal share for public transport.

TRANSPORT PLANNING IN DUBLIN

The two most important documents produced by Dublin transport planning authorities in recent years were:

- The Dublin Transport Initiative (DTI) Final Report (1995);
- *A platform for change 2000–2016* (2001).

The DTI Final Report recommended an integrated transportation strategy for the Greater Dublin Area (GDA) for the period up to 2011. The Government of Ireland decided that the DTI strategy should provide the planning framework for the future development of the transport network for the GDA.

The DTI strategy concentrated on public transport enhancement, with extensions to the heavy rail system running along the eastern coast recommended, together with three new light rail lines and the establishment of bus corridors giving priority to the bus system. Demand management was tackled mainly through the strategy of ensuring that no free parking should exist within Dublin's central business district, thus effectively increasing the cost of travel for motorists into the city centre. The Dublin Transportation Office (DTO) was set up in 1995 to carry out the strategy as outlined in the DTI Final Report.

The DTO published the document *A platform for change 2000–2016* in 2001 as an update to the original DTI strategy. While some progress had been made in the intervening years in implementing the basic strategy, there had been considerable slippage in the implementation of elements of the strategy, especially with regard to major public transport infrastructure projects, including light rail and bus. Also, there had been unprecedented economic growth since 1995, leading to very large increases in traffic levels, resulting in much greater congestion.

The main factors influencing increases in the demand for travel are economic growth, increases in population, number of households, number of people in work, growth in car ownership and use. All of these factors have increased since 1991, the date of publication of the first interim DTI Report, and are predicted to continue to do so until 2016.

Table 1 illustrates these trends (DTO, 2001).

Table 1: Factors influencing traffic growth

Greater Dublin Area	**1991**	**1996**	**1999**	**2016**
Population (million)	1.35	1.41	1.46	1.75
Households (’000)	402	446	521	675
Employment (’000)	452	549	681	878
Unemployment rate (%)	16	12	6	5
Car ownership (per ’000 population)	247	292	342	480
% growth in GDP since 1991	–	42	79	260

As can be seen from the data in Table 1, car ownership in the GDA is predicted to almost double in the 25 years between 1991 and 2016, with unemployment cut by two-thirds, population growing by 30%, and the number of households increasing by almost 70%.

As a result of this projected growth in the number of households, the population and car ownership, Dublin city faces a rapidly increasing demand for travel up to 2016, the scale of which is illustrated in Table 2.

Table 2: Factors influencing traffic growth

Greater Dublin Area	**1991**	**1996**	**1999**	**2016**
AM peak hour	172	250	283	488
Off peak hour	107	157	179	256

By 2016, therefore, it is predicted that total peak hour trips will increase by 95% on its 1996 level and by more than 180% on its 1991 level.

In order to deal with these projections, the 2001 document indicated a strategy with two independent elements:

1. **Infrastructure and service improvements**: to increase the supply of transport, including a substantial expansion of the public transport network, some strategic road construction and traffic management.
2. **Demand management**: to reduce the growth in travel through the application of land use and other policies while maintaining economic progress, and which is designed to encourage a transfer of trips, especially at peak periods, from the private car to sustainable modes of transport (bus, rail, cycling and walking).

Therefore, unlike the 1995 DTI document, the 2001 strategy makes explicit reference to demand management being a major part of the transportation strategy for Dublin city.

In 2004, Booz Allen Hamilton completed the document *Greater Dublin Area travel demand management study* for the Dublin Transportation Office in order to progress the demand management element of the 2001 DTO strategy.

Booz Allen Hamilton summarized the problems to be tackled by traffic demand management applied to the Greater Dublin Area:

- Consistent dispersion of the population of the past 25 years, resulting in less sustainable settlement patterns for public transport, leading therefore to a high mode share for private car use. As a result, in 2002, 80% of morning peak hour trips made outside the M50 C-ring motorway (located approximately 10km west of the city centre) are by car.
- The modal share of trips to school/work by car is increasing.
- The overall number of trips made to work by car is increasing.
- In 2002, 50% of all people travelling to work in the central Dublin area did so by car.
- In the future, average car speeds are forecast to decline throughout the GDA, indicating increasing levels of congestion.

To address these problems, Booz Allen Hamilton proposed a package of traffic demand management measures which would:

- influence land use planning, leading to more sustainable and less car dependent settlement patterns;
- facilitate drivers wishing to reduce their car usage; and
- strongly discourage unnecessary car usage in certain areas where alternative modes of transport are available.

The preferred package put forward by Booz Allen Hamilton, as well as proposing land use planning measures such as the promotion of the consolidation of population growth in existing built-up areas and the development of land in close proximity to public transport corridors, and travel demand management measures such as the implementation of workplace travel plans, proposes a city centre congestion charge of €10 applicable between 7am and 10am within Dublin’s central business district.

The remainder of this paper assesses the viability of this fiscal measure. First, other cities with a congestion charge in place are examined in order to evaluate how effective such a policy might be. Secondly, the willingness of Dublin’s drivers to pay the charge is assessed on the basis of a survey carried out by the authors. Finally, using the DTO’s transportation model for Dublin, the authors assess the effect of such a congestion charge on the pattern of morning peak car usage.

REVIEW OF CITY CORDON ROAD PRICING SCHEMES

Schemes currently in operation

London

Congestion charging was introduced into central London in February 2003. As of 2006, London is the largest city to have adopted a congestion charge. It was decided to introduce congestion charging because London had suffered traffic congestion levels among the worst of any European capital city, with drivers in central London spent 50% of their time in queues: every weekday morning the equivalent of 25 busy motorway lanes of traffic attempted to enter central London. It was estimated that London was losing approximately £2–4 million (€3–6 million) every week in terms of lost time caused by congestion.

London operates a cordon-based pricing scheme where drivers must pay to enter the central charging zone, i.e. the Central London area. The fee was originally set at £5 (€7.30) but from 4 July 2005 was increased to £8 (€11.70). The hours of operation are 07.00 to 18.00, Monday through to Friday. Payment can only be made in advance or after the trip is complete, with no payment possible at the cordon control points.

The main aims of the scheme are:

- to reduce congestion in the London area;
- to make radical improvements to the bus services by using revenue collected from tolls to fund improvements to public transport;
- to improve journey time reliability for car users;
- to make the distribution of goods and services more efficient;
- to improve the air quality and reduce levels of harmful emissions and particulates.

The main benefits of the scheme are:

- the scheme generates net revenues of about £100 million – 80% of which is spent on improving bus services within London;
- congestion inside the charging zone reduced by 30%;
- 30% reduction in number of cars and 65 000 fewer car movements;
- 20% increase in movements by buses, coaches and taxis;
- increase of 29 000 bus passengers entering the zone during morning peak.

Bus reliability and journey times improved – the additional time passengers wait at bus stops caused by service delays or missing buses improved by 20% across all of London and by 30% in and around the charging zone.

Rome
Again, this is a cordon-based pricing scheme where drivers must pay to enter the central charging zone, the historical centre of Rome. It was introduces in 1998, the main aim being to reduce traffic in the central area of Rome. Access to the area is free to residents. Other vehicle users purchase a special annual permit which allows them to drive through any of the access gates to the historical centre. Hours of operation are 06.30–18.00 Monday through to Saturday and as of October 2006 restrictions in the very central core will also be applied between 23.00 and 03.00 on Fridays and Saturdays. Plans are underway to expand the current city centre charging zone to the S. Lorenzo and Trastevere districts of Rome with a similar charging scheme being introduced.

The main benefits of the scheme are:

- decrease in traffic of 20% during hours of operation;

- annual payments for permits are in the region of €10 million.

Bergen
This is again a cordon-based pricing scheme where drivers must pay to enter the central charging zone. Introduced in 1986, its main aims are:

- to collect funds for road investments, with some contribution made to public transport;
- to reduce number of vehicles on most congested roads in morning and afternoon rush hours, by 10–15%;
- to improve journey times for cars and buses in the inner part of the city;
- to reduce air pollution.

Only ingoing traffic is charged for entering the cordon (city centre). The hours of operation are weekdays, 06.00 to 22.00. The scheme is currently in operation with a charge of 15NOK (€1.85) for traffic weighing up to 3500kg (cars) and 30NOK (€3.68) for traffic weighing over 3500kg (trucks).

The main benefits of the scheme are seen as significant revenue generation, along with a 7% decrease in traffic volumes during the day.

Oslo
This is again a cordon-based pricing scheme where drivers must pay to enter the central charging zone. Introduced in 1990, its main aim is to collect funds for road investments, with some contribution made to public transport.

The scheme operates on the basis that only ingoing traffic is charged for entering the cordon (city centre). Hours of operation are 24 hours a day 7 days a week. The scheme is currently in operation with a charge of 20NOK (€2.45) for traffic weighing up to 3500kg (cars) and 40NOK (€4.90) for traffic weighing over 3500kg (trucks).

The scheme is seen as generating substantial revenue, in tandem with reduction in queuing and delays and better road safety. Initial public opinion was not in favour; now 70% back the scheme. Furthermore, surveys would seem to indicate that initial negativity towards the scheme tends to dissipate once the benefits of its operation are felt by the residents. But would this also be the case with Dublin.

Durham
Durham has a cordon-based system where Durham’s peninsula can be accessed by a single road only. The charge is payable on exit from the area. Introduced in 2002, the main aims of the scheme are as follows:

- improvement in pedestrian safety;
- improvement in access for the disabled;
- enhancement of a World Heritage site;
- sustaining the viability of the city centre.

The scheme operates as follows. Traffic leaving the central area during the hours 10.00–16.00, Monday through to Saturday is charged. There is currently a charge of £2.00 (€2.95) to leave the cordon area during the hours of operation.

The revenues generated are used to support a frequent bus service to and from the charging area. There is a reduction of 85% in vehicular traffic with a 10% increase in pedestrian activity, with 83% of businesses having altered their servicing arrangements following the introduction of the charge.

Comment on effectiveness of schemes in place in other European cities
The majority of the above schemes generate substantial revenues in tandem with bringing about major reductions in congestion within the city centre. Surveys seem to indicate that initial resistance from the public seems to dissipate once the benefits of the scheme are felt by the city's inhabitants.

THE FINANCIAL BENEFITS OF A CONGESTION CHARGE WITHIN DUBLIN CITY

The costs of implementing the congestion charge
Table 3 details the costs associated with the introduction of congestion charging to Dublin as detailed by Booz Allen Hamilton (2004).

Table 3: Costs associated with congestion charging

Capital costs	**€ million**
System set-up – over three years	50
Complementary traffic management measures – over two years	44
Education/awareness programme – once off	5
Recurring costs	
Scheme administration – annual	5
Scheme operations – annual	60–120

They are seen to comprise a set-up charge of three years of €50 million, with the implementation of complementary traffic management measures costing €44 million and a once-off costing of €5 million for an education/awareness programme. Annual costs to cover the administration and operation of the scheme come to between €65 and €125 million per year.

The revenues projected from the introduction of the congestion charge
On the basis of a €10 congestion charge, levied between 7am and 10am, with a consequent reduction of 31% in vehicle movements within the cordon area assumed, the revenues estimated by Booz Allen Hamilton are detailed in Table 4.

Table 4: Annual revenues associated with congestion charging

Annual revenues	**€ million**
Congestion charge fees paid by vehicles crossing cordon	144
Congestion charge paid by residents within cordon	94

They are seen to comprise annual revenue of €144 million from the congestion charge payable by those crossing the cordon to enter the central business district, plus annual revenue of €94 million from the fees paid by residents living within the central business district. Thus total revenues from the congestion charge are predicted to be €238 million per year, a minimum of almost twice the annualized equivalent of the predicted initial set-up and ongoing operating costs.

If, as in the case of the London congestion charge, certain groups of drivers were to be exempted from the charge or have the charge heavily discounted, this could reduce revenue by up to one-third. However, even under this scenario, the financial case for the imposition of such a charge remains strong.

WILLINGNESS OF DUBLIN MOTORISTS TO PAY CONGESTION CHARGE

Introduction

While the financial argument for the imposition of the congestion charge would appear strong, it is important to gauge the willingness of Dublin motorists to pay any such charge imposed on them.

To this end, the authors undertook a survey of 100 motorists entering the Dublin central business district. Carried out during the period October to November 2006, the results point to the general opinion of car users who may be subjected to the charge.

The survey findings

The main questions the survey programme sought to answer were:

- whether people would be willing to pay a charge to cross the cordon at the entrance to Dublin's central business district if it meant less congestion on the roads; and if so
- what level of charge would they be willing to pay.

The survey also wanted to establish the number of trips those surveyed were making into the city every week and for what purpose.

Results indicated a majority of commuters driving into the CBD five days a week (57%) with the purpose of the trip for most drivers being the journey to work (67%).

When asked 'How much would you be willing to pay to drive into the Central Dublin Business District (City Centre) if a congestion charge were imposed between the hours of 7.00am and 10.00am?', the responses were as shown in Table 5.

Table 5: Willingness of Dublin motorists to pay congestion charge

Charge (€)	Willingness to pay charge (%)
0	100
1.5	90
2.5	83
5	50
7.5	20
10	10
15	0

Table 5 indicates that 50% of those commuting into Dublin by private car would be willing to pay a congestion charge of €5, with 20% willing to pay €7.50 and 10% willing to pay the €10 charge proposed by Booz Allen Hamilton.

While revealed preference surveys such as this have historically tended to underestimate the willingness of respondents to pay for the good being surveyed, the results do confirm a reasonable level of willingness to accept the introduction of such a charge. Given that motorists travelling into the city centre of Dublin are willing to pay up to €2.50 per hour for on-street parking, it would be reasonable to assume that the majority of the car-based commuters would be willing to pay a charge in the region of €7.50 to €10 for entering the city centre cordon at peak times.

In addition, the newly opened port tunnel in Dublin, bringing vehicles from the motorway C-ring on the western outskirts of Dublin into the port area in the city centre, is free for trucks but charges cars €12 during peak times and €3/€6 during off-peak periods. Latest figures indicate that 22% of the users over the entire 24-hour period are private car-based.

To conclude, based on data from the willingness-to-pay survey, it would be reasonable to assume that a charge in the region of €7.50 to €10 would be broadly acceptable to a reasonable proportion of car-based commuters, with data from the Port Tunnel indicating motorists willing to pay a toll in excess of this charge.

Given that a level of acceptability exists among car-based commuters with regard to the imposition of such a charge, what needs to be examined next is the level of congestion reduction that would result from the imposition of such charges in Dublin city.

RESULTS FROM DTO TRANSPORTATION MODEL

With the cooperation of senior personnel in the DTO, the authors utilized the DTO Saturn transportation model for Dublin to assess the effect of different levels of congestion charging on the modal share within the central business district of the city.

The model was run for three congestion charge levels, €0, €7.50 and €15. The assessment was completed on the basis of the existing transportation network within the city. No proposed road or public transport improvements were factored into the analysis. The €0 charge thus represents an analysis of the baseline/existing situation.

Table 6 indicates the changes in modal share for private cars entering the cordon at the entrance to the central business district between the hours of 7am and 10am weekdays for the three proposed charges. Table 7 indicates the changes in modal share for private cars within the cordon area between the hours of 7am and 10am weekdays for the three proposed charges.

Table 6: Effect of congestion charges on no. of cars attracted into city centre area

Modal share and total no. of car-based trips attracted to city centre area	**Modal share (%)**	**Total no. of vehicles**	**% Reduction in no. of vehicles**
Charge		0700 to 1000 weekdays	
€0	54	84110	–
€7.50	45	68299	19
€10	32	48824	42

Table 7: Effect of congestion charges on no. of cars attracted into city centre area

Modal share and total no. of car-based trips within city centre area	**Modal share (%)**	**Total no. of vehicles**	**% reduction in no. of vehicles**
Charge		0700 to 1000 weekdays	
€0	53	97606	–
€7.50	45	82011	16

€10	35	63203	35

Thus, a charge of €7.50 will result in a reduction of 19% in the number of cars entering the CBD and 16% in the total number of car movements within the area, while a charge of €15 will result in a reduction of 42% in the number of cars entering the CBD and 35% in the total number of car movements within the area.

By interpolating between the results obtained for the €7.50 and €15 congestion charges, it could be reasonably inferred that a charge of €10, as put forward by Booz Allen Hamilton (2004) will bring about a reduction in car usage levels of approximately 30%, along the lines of the reductions obtained in London.

CONCLUSIONS

In recent years, transport planners in Dublin have begun to consider the feasibility of introducing a congestion charge in the city's central business district. Experience in other capital cities points to the effectiveness of such schemes in reducing car usage at peak weekday times. Use of the DTO's transportation model for Dublin indicates that the imposition of a €10 charge at peak times will lead to a reduction of approximately 30% in car usage within the city centre. While surveys of Dublin motorists indicate a limited willingness to pay this level of charge, such surveys would tend to be overly conservative in their predictions. This proposition is supported by data from the newly opened Dublin Port Tunnel, where car-based commuters are willing to pay a charge of €12 at peak times. Furthermore, as the public transport infrastructure within the Greater Dublin Area improves, particularly with the completion of the proposed Metro system, resistance to the imposition of a congestion charge will diminish as commuters are given viable and efficient alternative modes of travel into the city centre.

ACKNOWLEDGEMENTS

The help and cooperation of the Dublin Transportation Office in the production of results for this paper is greatly appreciated by the authors.

RISK ASSESSMENT IN CONSTRUCTION COST ESTIMATION OF A MOTORWAY PROJECT

Giray Kumas[1] and S. Ergonul[2]

Construction projects face substantial and unique risk factors at every stage. These factors threaten the project targets unless the uncertainty is moved away from the project. Risk management is one of the most effective systems in order to optimize performance and minimize the risks involved in a project. This process has to be realized and considered in every stage of a project. This study presents potential risks that cause an increase in the total construction cost and analyses how construction risks are assessed in a motorway project. Construction risks are considered from the contractor's point of view. First, real forecasts of the motorway project provided by the contractor are analysed in order to define contractor's risk policy. Then, the existing risks are assessed by a probabilistic, Monte Carlo simulation method using crystal ball software. The results of the simulation method are compared with the results of the actual situation. The results show that simulation method helps the contractors to manage the costs with high risk.

Keywords: cost, estimating, risk, simulation.

INTRODUCTION

Construction projects are characterized as very complex projects, where uncertainty comes from various sources (Miller and Lessard 2001). These projects are characterized by continuous decision making due to numerous sources of risk and uncertainty, many of which are not under the direct control of project participants (Baloi and Price 2003). Risks associated with construction projects are potentially serious and have high financial and social impacts (security/safety, reputation/image, quality of life, etc.) on major parties involved in the project, such as the owners, consultants, contractors, subcontractors, suppliers, insurers or financiers (Taş 1994). Construction projects have a bad reputation of failing to meet the deadlines and cost targets (Mills 2001). That is why identifying risk sources is extremely important, since it is not necessarily possible to identify every single risk.

There are a great number of risks associated with construction. Cohen and Palmer (2004) identified risk trends in construction projects. They found that typically, risks are determined at the very early phases of the project (feasibility and planning) while the impacts are not experienced until the construction and production start-up phases. They list typical sources for risks in construction projects as technical, social, construction, economic, legal, financial, natural, commercial, logistical and political.

[1] giraykumas@yahoo.com

The effect of any of these risks eventually can be expressed in terms of monetary loss, property damage, personal injury or a combination of these.

Odeh and Battaineh (2002) studied the most typical reasons for construction delays in Far East construction projects. They found seven significant causes of delays: owner interference, inadequate contractor experience, financing and payments, labour productivity, slow decision making, improper planning and subcontractors. According to Mills (2001) three of the most important risks in construction projects are weather, productivity of labour and plant and quality of material. These areas are not easily controllable by a contractor before the project execution.

In recent years, thanks to the increase in technical complexity and the need for economic, environmental, legal and political viability present in modern society, concern over risk has been growing. This concern generates a need for effective risk management. The risk management process should be implemented at the early project phases, when there is still a possibility for fundamental changes (Chapman 1997). The project should be carefully analysed as to which kind of methods to use at which project phases and a process needs to be customized according to all project characteristics.

This study aims to analyse construction project risks which affect the total cost and to examine how risks are taken into account for a motorway project. Construction risks in cost estimation are considered from the contractor's point of view. Risks of the motorway project are assessed by practical and probabilistic approach.

RISK MANAGEMENT IN CONSTRUCTION PROJECTS

Ababneh (2000) expresses risk management as the science of optimizing performance and minimizing the risks involved in successfully completing a project. However, in order to optimize, it is also necessary to appreciate the nature and the consequences of the risk involved. A risk management process should therefore encompass all these functions.

The Project Management Body of Knowledge (PMBOK) (PMI 2000) details risk management processes as risk identification, risk analysis, risk response planning and risk monitoring and control. Risk identification is stressed by many researchers (Chapman 1997; Turner 1999; Chapman 2001). Identification of the risks should be the initial step in all projects. After risks have been identified, the next step is to evaluate them. This means establishing how serious the risks are, in terms of both their potential severity and extent, and their likelihood of occurrence or judgement measures. Risk response is defined by PMBOK (PMI 2000) as the process of developing options and determining actions to enhance opportunities and reduce threats to the project objectives. Literature (Turner 1999; PMI 2000) suggests that there are generally four response types to cope with risk:

- Avoid: change in project plans in a way that an identified risk is no longer relevant.
- Transfer: transfer risks to other parties by contracts or insurances.
- Mitigate: find ways to reduce the probability and/or impact of risk.
- Accept: take a conscious risk and deal with negative consequences as they occur, but take no action beforehand.

Risks in construction projects are a significant element of the total project costs and thus their allocation has a major effect on project budget (Zaghloul and Hartman 2003). Construction organizations operate within an environment and not a vacuum. They are inevitably influenced by and constantly interacting with their environment. Hence, construction projects are open systems, rather than closed systems, which adds to the variability and riskiness of the project (Baloi and Price 2003). The risk management process has to be adjusted to the cooperative environment, where multiple actors manage risks together in construction projects, but unfortunately this has not yet happened. Risk management in the construction industry still relies heavily on contracts, and the industry has the bad reputation of becoming involved in numerous disputes and claims. According to various studies (Baloi and Price 2001; Floricel and Miller 2001), contractual structures are the main sources of the lack of flexibility and they have a significant negative effect on the actor relationships. Apart from contracts, studies show that construction risks are mainly handled with experience, assumption and human judgement (Baloi and Price 2003).

CASE STUDY

In order to analyse how risks are considered in cost estimation, a case study is carried out. A motorway project which was executed in Croatia in 2002 is selected for the case study. The contractor of the project is a joint venture (JV). The names of the partners of the JV are not stated in this study to respect confidentiality. The type of contract between the JV and the employer is unit price and the scope of the project is a 220km motorway with viaducts, underpasses, overpasses and with a cost of US$950 million. In the case study, first the contractor’s risk policy is explained to analyse the actual situation. Then, a probabilistic approach to cost estimation of the motorway project is presented.

The contractor’s approach to risk

In the project cost estimation, forecasts provide a framework to analyse the present situation and also assist analysis of the short-term prospects. Forecast is a kind of calculation which is done periodically during the execution of the project. The period of the forecast changes depending on the contractor’s policy (once or twice per year).

In this study, real forecasts of the motorway project are taken into account to define the contractor’s risk policy in actual situations. The first forecast of the project is done immediately after signing the construction contract and six months later updated by Forecast 2 which is later on updated by Forecast 3. This study covers the second and third forecasts of the project because they are the only forecasts provided by the JV.

Table 1 shows the cost values of forecasts of the JV. Total cost consists of direct costs, indirect costs, provisional sum and management reserve. All the costs of the contractor are calculated in a forecast and updated by next forecasts throughout the project. Risks, which are identified throughout the project, are also analysed in this way, and their results are included in the forecast. As a result of each forecast, the contractor foresees remaining turnover, financial expenses and probable risks. Therefore, the contractor can decide which precautions need to be taken for the following periods. For example, intended cash flow can suffer many changes during the project. Financial risks can be assessed easily owing to forecasts for subsequent periods, and cash flow can be rearranged (Galipoğulları 2001).

Management reserve in the forecasts refers to potential risks considered in cost estimation. This reserve is a measure for accepted risks. In other words, it is a budget assigned by the JV for the risks and used in order to protect the cash flow against any adverse impacts of these risks.

A share is assigned for unforeseen risks in management reserve, and such share is called ‘Remaining contingency’ which is about 5% of direct costs depending on the JV’s experience. In the contract there is no clause for escalation; therefore, depending on the historical data the JV includes the risks of inflation and exchange rate in management reserve. ‘Section 1 borrow settlement’ is an existing dispute between the JV and employer. This dispute might be settled adversely for the JV, and the monetary size of its impact to cost is added to the reserve. For confidentiality reasons, detailed information regarding ‘Financial costs for $150M’ and ‘Potential unrealized value’ is not given by the JV. They are two foreseen risk items, and have been accounted for in management reserve. The JV realizes that the local wage rates are likely to increase more than the escalation. Other contingencies cover wage rates as well as quarries, land leases, transportation and so on.

Table 1: Cost forecasts of the motorway project, US$ million

Costs	FC 2	FC 3	FC3-FC2
Direct costs			
Labour	32.5	32.4	–0.1
Material	41.6	43.5	1.9
Subcontracts	126.4	147.9	21.5
Manufacturing	66.1	50.2	–15.9
Equipment	91.6	87.1	–4.5
Provisional sum	16.6	18.5	1.9
Indirect cost			
Non-manual cost (health insurance, taxes, etc.)	33.1	37.1	4.0
Camps and plant set-ups/Demo	28.0	31.7	3.7
Maintenance, transportation, meals, etc.	51.8	54.9	3.1
Equipment for maintenance	10.5	7.4	–3.1
Communications, office supplies, other office	13.3	12.6	–0.7
Customs, taxes, insurances, bonds	22.5	22.8	0.3
Subtotal cost	534.0	546.1	12.1
Management reserve			
Remaining contingency @ 5.0%	19.5	17.0	–2.5
Escalation	31.7	21.9	–9.8
Potential unrealized value	9.5	0.0	–9.5
Financial costs for $150M	1.5	0.0	–1.5
Section 1 borrow settlement	1.5	0.0	–1.5
Other contingencies	0.0	37.5	37.5
Total management reserve	63.7	76.4	12.7
Total cost	597.7	622.5	24.8

As explained above, some of the risks are included in management reserve. However, Table 2 presents the allocation of the other risks. As seen in Table 2, the JV chooses risk transfer for risks of ‘Accidents’, ‘Acts of God or government’, ‘Materials and equipment’ and ‘Safety at site’. All these risks are covered in insurance. Insurance may be the choice of the JV or the local legislations or the contract may require it for some risks. The JV accepts the risk of ‘Choice of subcontractor’, ‘Inflation’ and ‘Payment delays’ and assigns reserves for them in management reserve. There are also some risks that are allocated elsewhere but not provided by the JV such as ‘Poor site investigations’, ‘Defective work’, ‘Weather conditions’ and ‘Management incompetence’.

Probabilistic approach to risk

Estimates are probabilistic assessments, therefore costs may actually be higher or lower than estimated even by seasoned professional estimators. The reasons are often causes that are outside the control of the project manager, but may also be endemic to the estimating process, the project strategy or the corporate culture within the project contractor (Hulett 1999).

Table 2: Most probable risks undertaken by the JV

Type of risk	Type of risk response	Policy of the JV
Currency risk	Risk acceptance	Management reserve (escalation)
Payment delays	Risk acceptance	Contract (late payment interest clause)
Inflation	Risk acceptance	Management reserve (escalation)
Accidents	Risk transfer	Insurance (liability insurances)
Vague contract conditions	Risk acceptance	Management reserve (other contingencies)
Ambiguous specifications	Risk acceptance	Management reserve (other contingencies)
Defective drawings	Risk acceptance	Management reserve (other contingencies)
Acts of God or government	Risk transfer	Insurance (CAR & property insurance)
Choice of subcontractor	Risk acceptance	Management reserve (other contingencies)
Quantity variations	Risk acceptance	Management reserve (potential time ext.)
Materials and equipment	Risk transfer	Insurance (property insurance)
Labour problems & union strife	Risk acceptance	Management reserve (other contingencies)
Delays in the work	Risk acceptance	Management reserve (potential time ext.)
Safety at site	Risk transfer	Insurance (miscellaneous Insurance)

In the probabilistic approach Monte Carlo simulation is accepted as the probabilistic method and crystal ball is used to simulate the construction cost of the motorway project. There are three important issues in Monte Carlo simulation. The first one is to specify reasonable statistical distribution for any cost component subject to variation. The second issue is that cost correlations between individual components should be known and accounted for. The crystal ball software uses the Iman and Conover method for generating correlated random numbers. The third issue is the number of simulation runs.

Table 3 presents cost components, which are accepted as random variables in Monte Carlo simulation as they are responsive to any alterations in design and construction. Each cost component has its minimum, mean (most likely) and maximum values depending on Forecast 2 and Forecast 3. In the analysis of cost values of both forecasts it is seen that assigning a standard deviation to cost components is not possible because the minimum and maximum ranges are not symmetrical. Forecasts provide a greater likelihood for overruns than for underruns. The triangular distribution describes a situation where minimum and maximum values are known (Moran 1996). Therefore, triangular distribution with minimum and maximum values is satisfactorily assigned to cost components. In the evaluation of Forecast 2 and Forecast 3, it is assumed that a value which is 5% less than mean cost and a value which is 25% more than mean cost satisfactorily represent the minimum and maximum cost values respectively (Giray 2005).

In all simulation experiments conducted in this study, the results remained virtually unchanged after 3.000 runs. Therefore, running the model 5.000 times will provide a satisfactory distribution for the construction cost estimation.

Figure 1 shows the construction cost distribution for the motorway project. Table 4 summarizes the statistical results of the Monte Carlo simulation. The mean is US$582.2 million with a standard deviation of US$12.58 million.

Table 3: Cost components and their distribution, US$ million

Cost component	Minimum cost	Most likely cost	Maximum cost	Distribution
Labour	30.8	32.4	40.5	TRIANGLE DISTRIBUTION
Material	41.3	43.5	54.4	
Subcontracts	140.5	147.9	184.9	
Manufacturing	47.7	50.2	62.8	
Equipment	82.7	87.1	108.9	
Provisional sum	17.6	18.5	23.1	
Non-manual (health insurance, taxes, etc.)	35.2	37.1	46.4	
Camps and plant set-ups	30.1	31.7	39.6	
Maintenance, transportation, meals, etc.	52.2	54.9	68.6	
Equipment for maintenance	7.0	7.4	9.3	
Communications, office supplies, other office	12.0	12.6	15.8	
Customs, taxes, insurances, bonds	21.7	22.8	28.5	
Total estimated cost	518.8	546.1	766.5	

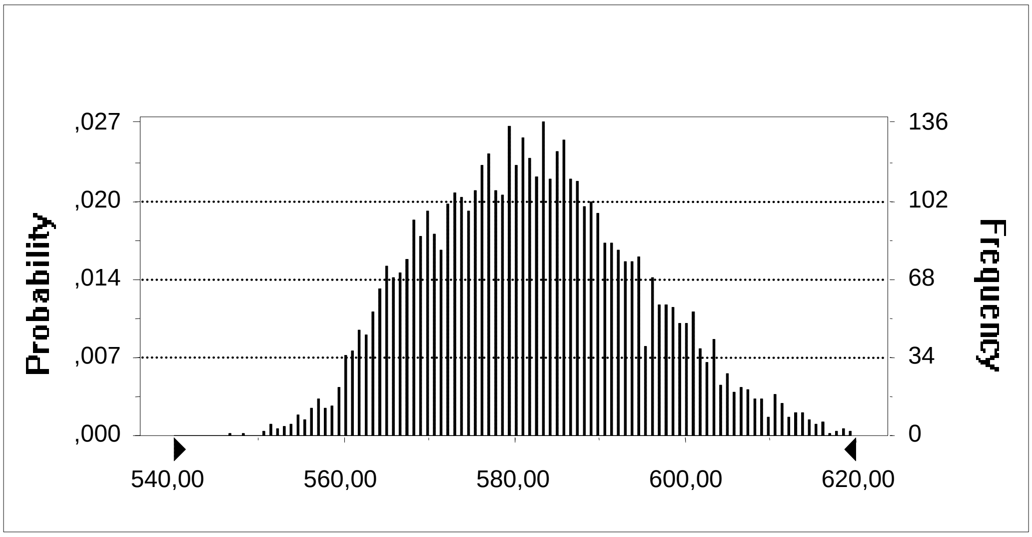

Figure 1: Probability distribution of the project cost, US$ million

Table 5 shows the probabilities of the construction cost that occurs. The probability of having a construction cost that is less than US$581.72 million is 50%. In order to cover existing risks, total construction cost is to be US$624.48 million. That means that almost US$77.58 million should be set aside in addition to the construction cost with no risk assigned.

Table 4: Simulation results for project cost estimation, US$ million

Statistics	Value
Trials	5.000
Mean	582.20
Median	581.72

Standard deviation	12.58
Variance	158.19
Coeff. of Variability	0.02
Range minimum	546.90
Range maximum	624.48

Table 5: Probability of the project cost

Percentile	Estimated cost of the project, US$ million
0%	546.90
10%	565.98
20%	570.72
30%	574.86
40%	578.44
50%	581.72
60%	584.97
70%	588.49
80%	592.89
90%	599.24
100%	624.48

Monte Carlo simulation enables us to identify the high-risk cost elements and rank them by their contribution to risk in the project (Hulett 1999). Sensitivity analysis of Monte Carlo simulation shows that construction cost is more sensitive to the cost components of subcontracts, equipment, maintenance and manufacturing as average 74%, 40%, 26% and 22% respectively. It provides less sensitivity to the equipment for maintenance and provisional sum.

Table 6 compares the simulated costs with actual recorded costs on the project. In the comparison of total project cost without any risk consideration and with possible risk consideration, the simulated results provide a reserve of $77.58 million while actual recorded reserve is $764 million. The results show that the probabilistic approach provides reliable results for the construction cost estimation.

Table 6: Comparison of simulation results with the actual recorded results, US$ million

Total project cost	Actual	Simulation
Without considering any risk	546.1	546.90
With considering risks	622.5	624.48

CONCLUSIONS

The construction industry is one of the most risky sectors owing to its dynamic and unique characteristics. A highly competitive environment makes contractors assume many risks on their own. These risks may affect contractors in many ways and cause high financial and social impacts.

In this study possible construction project risks and their allocation are discussed. Construction contracts may help to mitigate project risks but there are many risk factors that cannot be referred to construction contracts and usually the allocation of risks with any other method presents additional costs. The correct allocation method has to be defined and established successfully in order to save the project finance.

Risk assessment of a motorway project is analysed by actual and probabilistic approach. A dynamic risk management process is established in practice. Transferred risks are covered by insurance. However, for accepted risks identified during the project, reserves are assigned in order to save the project finance. In the comparison of actual results with simulation results, Monte Carlo simulation presents reliable results if the maximum and minimum values of the simulation are estimated accurately.

USING PROJECT LEARNING TO ENHANCE THE VALUE OF CONSTRUCTION PROJECTS

Hamzah Abdul-Rahman,[1] Mohd Suhaimi Mohd Danuri, Low Wai Wah, Norhanim Zakaria and Faizul Azli Mohd Rahim

Center of Project and Facilities Management (PFM), Faculty of Built Environment, University of Malaya, 50603 Kuala Lumpur, Malaysia

Project learning has captured the attention in the construction industry as a means to share and acquire knowledge. Loss of knowledge gained over the years and unavailability of relevant knowledge at the project phases are typical issues in the construction industry. A study was conducted to explore the learning practice of contractors and to determine how project learning can enhance the value of construction projects. The research was focused on pre-construction stage and targeted the larger groups of contractors. Quantitative and qualitative methodologies were employed in the study. Preliminary findings indicated that project level learning is spontaneity and highly individualized, periodic meeting and informal communication are usual modes of learning, and lesson learned is seldom disseminated to project-related parties during the execution of project. Questionnaire survey uncovered that learning in construction is less formalized, and discussion and knowledge sharing among project team are capable to enhance project value. Findings indicated the need to focus on learning process and establishing a practical system to capture knowledge. A model was proposed for continuous project learning to assist organizations in realizing the quest and utilization of project knowledge.

Keywords: construction, knowledge, project learning.

INTRODUCTION

Construction is a project-oriented and knowledge-based industry (Fong and Chu 2006). Each construction project is rich with significant learning opportunities (Eliufoo 2002). Getting the full value from these characteristics of the industry should advance the industry a step forward. Nonetheless, construction industry seems to move backward (Kadefors 1995; Woudhuysen and Abley 2004) and there is a need to offer added value to the customers and the society (Kristiansen *et al*. 2005).

Value is increasing emphasized in today's world (Rowlinson 2005) and construction is not an exception. Value is typically defined as the cost of least expensive way to deliver the desired functional performance (Watson 2005). Improving value ensures quality, reliability, performance, and other critical factors of a project meet or exceed customer's expectations (Dell'Isola 1997). A project is considered value for money to the client if specifications related to time, cost and quality are achieved.

Issues of low quality, delay and cost overruns (Hussein 2003; Abdul-Rahman and Berawi 2002; Abdul-Rahman *et al*. 2006) are still common in the Malaysian construction industry. A survey discovered that lack of knowledge contributes a role in construction project failures (Leong 2006). Another survey found that unavailable

[1] arhamzah@um.edu.my

of relevant knowledge throughout the project phases is the reason behind the lack of constructability (Nima *et al*. 2002). Accordingly, learning within a project relates to project success or failure and may affect the value of the project (Storm and Savelsbergh 2005) as new knowledge is needed constantly to improve the value of future projects.

Project learning emerges as a vital approach in knowledge-based development which concerns with the set of actions used by project teams to create and share knowledge within and across projects (Kotnour 2000). It is an important value driver in construction projects as current post project evaluation is doubted in its ability to capturing and reusing of lessons learned (Kamara *et al*. 2003, 2002). Moreover, construction professionals and policy makers seem to have failed to implement knowledge sharing among projects parties (Hussein 2003; Berawi 2004).

LITERATURE REVIEW

Learning becomes an attentive issue in the construction industry either at the organizational level or at the project level. Methods used in knowledge management (Carrillo 2004; Bresnen *et al*. 2003; Carrillo *et al*. 2004), knowledge transfer (Eliufoo 2002; Brochner *et al*. 2004), knowledge sharing (Fong and Chu 2006), organizational learning (Kululanga *et al*. 1999; Love *et al*. 2003) and project learning (Gieskes and Broeke 2000; Fong and Yip 2006) have been the dominant focus to many researches. These researches provide contribution of knowledge on a list of methods of managing knowledge and learning in the construction industry. However, researchers give less attention on the learning initiative especially in developing nations, like Malaysia. Chan *et al*. (2005: 747) raised a question “whether organizational learning at the construction project level is applicable”. This thought touches the future scope of research to explore whether organizational learning methods can be fully adopted at the construction project.

Some studies looked at the benefits of learning and knowledge initiatives (Puddicombe 2006; Fong and Chu 2006). These researches make a good point of departure in an academic research as less empirical studies, either qualitative or quantitative, focus on the advantages of learning and knowledge initiatives.

Other studies have focused on practical-related problems including to develop learning and knowledge initiative models (Fong 2003; Kamara *et al*. 2003; Robinson *et al*. 2004; Tserng and Lin 2004; Lin *et al*. 2005). Nevertheless, there is scarcity of developed models that looks into the subject of continuous learning. This subject is important as lack of standard work process constitutes a main barrier for the application of knowledge management in the construction (Carrillo *et al*. 2004; Carrillo 2004). This implies the danger of knowledge loss and the need of a standard framework to ensure that learning and knowledge can effectively take place.

RESEARCH AIMS, OBJECTIVES AND SCOPE

Based on issues confronting the construction industry and the previous literatures voids, the study aims to review project learning practices and benefits gained by contractor organizations during pre-construction stage. The objectives include:

1. To identify the current project learning approaches among local contractors and to determine whether organizational learning methods can be fully adopted as construction project learning method.

2. To find out the major elements that can be significantly improved through project learning exercise; and
3. To develop a continuous project learning model.

MODEL DEVELOPMENT

Comparison to some existing developed models

A continuous project learning model is proposed based on three basic principles, namely, knowledge management, continuous collaborative learning and lesson learned. The principal intention of the proposed model is to enhance learning and project knowledge management in the construction projects. In Fong's (2003) study, three knowledge processes of knowledge sharing, knowledge generation and knowledge integration are highlighted and collective project learning is considered as the central to the three knowledge processes. Kamara *et al*. (2003) focused on the live capture and reuse of project knowledge and recommended the use of learning histories, collaborative learning, project extranets and workflow management. Robinson *et al.* (2004) suggested the integration of knowledge management strategy into business case in construction organizations. Tserng and Lin (2004) and Lin *et al*. (2005), on the other hand, addressed the use of knowledge management by contractors in the construction phase. Table 1 shows the focus areas of knowledge management between the proposed model and existing developed models.

Table 1: Comparison of the proposed model to others existing developed models

Theoretical perspectives of the developed model

The theoretical perspectives of the developed model are based on the integration of team learning theory (including individual learning reviews, functional learning reviews, whole team learning review and communication of learning) from Barker and Neailey (1999) and learning process theory (including focus, environment and techniques) from Buckler (1996). Based on these theories, seven aspects were taken into account in the development of the proposed model as follows: (i) learning goal setting; (ii) storytelling; (iii) brainstorming; (iv) reflection; (v) feedback; (vi) knowledge exchange protocol; and (vii) web-based tools.

Proposed continuous project learning model

Figure 1 represents the eight phases of the proposed continuous project learning model during pre-construction stage.

1. Identify subject matter: involves the identification of subject matter in respect to project risks, problem faced or knowledge gap due to the project constraint.
2. Identify learning goals: composed of identification of learning goals based on the expected value and project requirements.
3. Source of knowledge: project team members explore knowledge base of the subject matter and learning goals to identify the available and unavailable knowledge. In general, knowledge base is divided into tacit and explicit form of knowledge.
4. Knowledge sharing session: contains group discussion in the form of brainstorming, reflection, questioning and multi-way feedback sessions.
5. Knowledge application: make and evaluate decisions based on the generation of new knowledge.
6. Knowledge filter and storage: filter and store valuable knowledge generated during the knowledge sharing session in a standard template database that contains project name, subject matter, keywords, expert information and knowledge protocol.
7. Knowledge dissemination, retrieve and update: all project parties communicate and retrieve pertinent knowledge or lesson learned through web-based tool. Knowledge protocol is updated at the end of each knowledge sharing process.
8. Lesson learned linkage: form a continuous learning cycle where any lesson learned, principals or new knowledge from past discussion are linked to subsequent discussion to improve the value of the decision making.

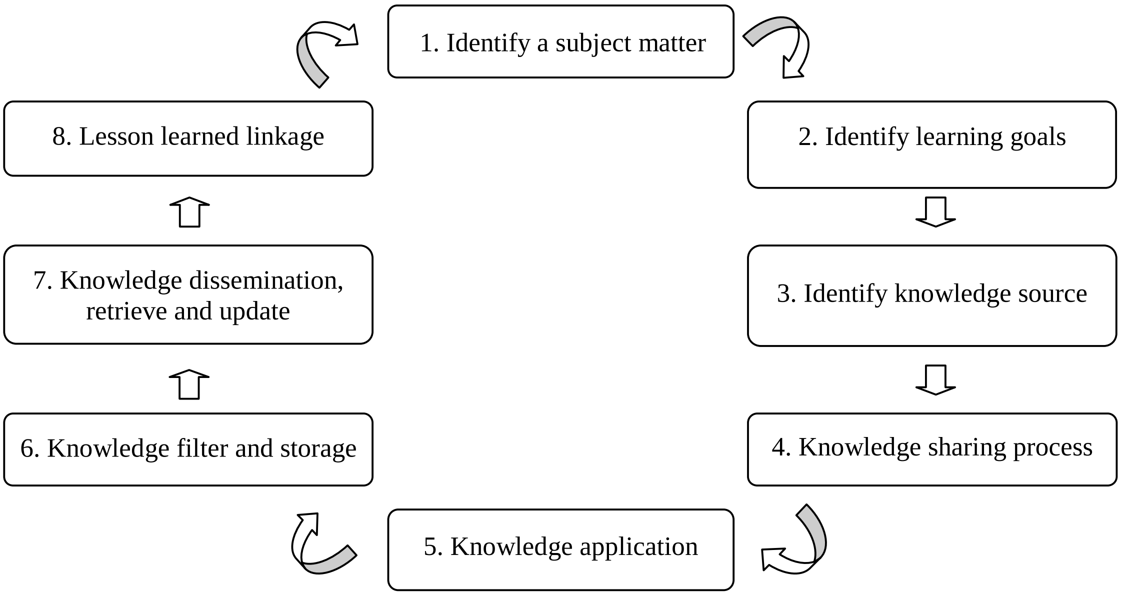

Figure 1: Continuous project learning model

RESEARCH METHODOLOGIES

The study ongoing stage and the research methodologies included the use of literature survey, preliminary interviews and questionnaire survey. Literature survey was performed to outline the current issue in the construction relating to the research area, to find out the knowledge gaps in the pertinent research area, to formulate questionnaire and interview design, and to identify relevant theoretical and empirical information on organizational learning, project learning and learning advantages.

Preliminary semi-structured interviews were conducted for the purpose of exploratory research to extract point of view from contractor firms to understand the existing learning environment in construction projects, to identify the learning methods employed in construction projects and to identify benefits of learning practice. Seventeen construction professionals were randomly selected to participate in the preliminary interview. Preliminary interviews were conducted among a general manager (1), project director (1), project managers (5), contract manager (1), engineers (2), quantity surveyors (6) and administrative executive (1) with two to more than 20 years of experience in construction.

Quantitative questionnaire was selected to collect factual evidence about the organizational learning methods, learning practice in project environment, benefits of each learning methods and the validation of the developed model. The questionnaire method was chosen as it assists the study to generalize findings from a sample to a finite population (Hammersley and Gomm 2000) within a limited time frame (Naoum 1998).

Contractors from Grade 5 to Grade 7 registered with the Malaysian Construction Industry Development Board (CIDB) were targeted as they are involved in a wide range of small to large-scale projects. The study was based on probability stratified sampling method to guarantee adequate representation of groups (Weisberg and Bowen 1977) and the reliability of the sampling design is supported by methods employed in previous studies (Gieskes and Broeke 2000; Love *et al*. 2003). A sample size of 2000 (approximately 27% of total population) private contractor firms in Malaysia was empirically studied. This sample size is considered adequate and excessive based on the sample size table developed by Krejcie and Morgan (1970). The website and the 2005/2006 CIDB directory were used as the sampling frame.

A pilot questionnaire in reference to previous studies (Kululanga *et al*. 1999; Gieskes and Broeke 2000; Fong and Chu 2006) in the field of organizational learning and knowledge management was carried out on a pilot study of 16 construction professionals. The pilot study was conducted either in the semi-structured interviews or in postal survey based on respondents' preferences. Parties participated in the pilot study included project directors (2), project managers (4), contract manager (1), engineers (4) and quantity surveyors (5).

Frequency distribution, percentage distribution and mean were adopted to present the nominal and interval data in an understandable manner. Friedman test, Chi-square and Eta were selected as inferential tests to analyse significant of nominal and interval variables, and the association between nominal and internal data. Data was analysed using Statistical Package for the Social Science Version 13 (SPSS 13.0).

SUMMARY OF PRELIMINARY INTERVIEW FINDINGS

Organizational learning methods

Interviewees were not in general agreement as three interviewees perceived that organizational learning methods can be fully adopted as project learning methods. Fourteen interviewees expressed contrasting views and highlighted that the use of organizational learning methods in construction projects would depend on the project characteristics, size and complexity, the extent of effective of the methods, the capability and willingness of the organization, and the available resources.

Project learning methods
Face-to-face interaction, project meeting, brainstorming, on-the-job training, helping others and referring to previous project were found to be the common methods used by the professionals in the construction.

Improvement elements via project learning practice
Benefits specified by interviewees including encourage individual improvement in respect of knowledge and proficient of task, step up the project value in terms of time, cost and quality, and avoid of “reinvent the wheel”. Few interviewees further commented that the advantages of learning depend on types of information and knowledge, people involved and the types of learning methods.

SUMMARY OF QUESTIONNAIRE FINDINGS

Demographic information
A total of response rate of 5.9% was achieved for the questionnaire survey. Among the respondents, 24 (20.3%) were directors, 12 (10.2%) were general managers, 29 (24.6%) were project managers, 9 (7.6%) were contract managers, 19 (16.1%) were quantity surveyors, 16 (13.6%) were civil and structural engineers and 9 (7.6%) survey respondents held others positions.

Organizational learning methods
Table 2 shows that approximately 65% or above of the total respondents recommended that all the listed organizational learning methods can be implemented in construction projects. Organizational learning methods with response rate of 90% and above include knowledge communities (98.30%), mentoring (97.5%), education (96.6%), professional forum (94.9%) and network of practice, reuse of expert and benchmarking (90.7%). Organizational learning methods that were below 75% were partnering (64.4%), usenet newsgroup (67.8%), electronic conference (69.5%), electronic meeting and chat tools (71.2%) and group document handling (74.6%).

Eta correlation value demonstrates that 13 variables show a medium association and 14 variables shows a high association between the respondents’ recommendations and the extent of effective of the method in knowledge acquisition. Accordingly, variables with 3.50 and above of effective mean value include: education (3.86), mentoring (3.82), knowledge communities (3.72), reuse of expert (3.58), coaching and professional forum (3.58). In contrast, variables with effective mean value below 3.00 include: usenet newsgroup (2.76), chat tools (2.79), electronic conference (2.86), electronic meeting (2.90) and partnering (2.97).

Project learning methods
Table 3 displays the statistical result on the application of learning methods in construction projects. Of the total 118 respondents, learning methods that made up a large proportion of the total response, that is 85% and above were periodic meeting (94.9%), informal face to face interaction (93.2%), problem solving techniques (91.5%), documentation learning (92.4%), internet information searching (89.8%) and imitation (87.30%). Chi-square test for Goodness-of-Fit confirmed that there were significant differences in the results with p-value less than 1% level of significance.

Table 2: Recommendations and effectiveness of organizational learning methods

Improvement elements via project learning practice

Table 4 opposite illustrates that not all the learning methods that are commonly applied in construction projects are able to provide a high positive impact towards project value. Five learning methods were perceived as effective approaches if implemented during the pre-construction stage: imitation, informal face-to-face interaction, periodic meeting, problem solving techniques and on the job training. Project constructability was the sole benefit that could significantly be improved among the implementation of five ideal learning methods during the pre- construction stage.

Developed continuous project learning model

Table 5 presents the results of the useful extent of the developed continuous project learning in several aspects. The mean value of the each criterion was sequencing as follows: enhancing knowledge sharing (4.30), enhancing learning and improving individual knowledge seeking (4.26), enhancing communication (4.21), applicable to the current construction projects (4.19), reducing similar mistake (4.14), reducing unnecessary time (4.07) and reducing unnecessary cost (4.04). Friedman test showed that the Chi-square value is 40.583 with p-value less than 1% level of significance. It can be concluded that the developed continuous project learning model is more capable in enhancing knowledge sharing, enhancing learning and improving individual knowledge seeking with mean value above 4.25.

Table 5: Model validation

Validation criteria	Max.	Min.	Mean	Standard deviation	Rank
Applicable to construction projects	3	5	4.19	0.574	4
Enhancing communication	2	5	4.21	0.568	3
Enhancing learning	3	5	4.26	0.633	2
Enhancing knowledge sharing	2	5	4.30	0.618	1
Improving individual knowledge seeking	2	5	4.26	0.646	2
Reducing similar mistakes	1	5	4.14	0.761	5
Reducing unnecessary time	1	5	4.07	0.725	6
Reducing unnecessary cost	2	5	4.04	0.778	7

Friedman test: Chi-square = 31.122, significant, p = 0.001

DISCUSSION

Survey results illustrate that the proposed model tends to be more capable to enhance learning, knowledge sharing and individual knowledge seeking in the construction industry. Drawing on existing arguments, increased profit (Macher 1992) and increased knowledge, which may be either tacit or explicit (Rowley 2000) are after-the-fact indicators that learning is occurring. Accordingly, Winch (2002) affirmed that effective learning within the project deploys the new value creation to the project. Thus, it can be expected that the application of the proposed model during the pre-construction stage is capable to enhance the value of construction projects in terms of time, cost or quality. Nevertheless, it is the significant value of the project is difficult to foresee in reality due to environment, human and other unforeseen factors.

The strength of the proposed model is that it focuses on project knowledge and continuous collective learning in which both elements are critical in enhancing the value of the construction projects. However, the potential shortcomings of this model are that it is built on an unproved premise and the model seems to be suitable for moderate large and complex construction projects.

A three-group classification was used based on the average score as follows:
i. Low positive impact (0.00 ≤ mean ≥ 0.67)
ii. Medium positive impact (0.67 < mean ≥ 2.34)
iii. *High positive impact (2.34 < mean ≥ 4.00)

CONCLUSIONS

Although construction industry is fragmented in nature, it has the strength and capability to implement project learning effectively. Results of the survey suggest that: (i) learning within project environment in inter-organizational setting need to be emphasized and top management should play an active role; (ii) a practical system to capture project knowledge is essential; (iii) commitment integration supplements with good leadership from local authority, construction professional and clients play a critical role to the successful implementation of project learning; and (iv) to improve the value of future project, project learning should be integrated into education system to cultivate a conducive learning culture among the junior generation.

The present study demonstrates several limitations, namely: (i) the study was restricted in scope to the local contractor firms in Malaysia; (ii) the study focused only on the preconstruction stage; and (iii) the findings of the questionnaire survey was in infancy stage as the research is in the stage of collecting follow-up data from the non-response respondents and conducting case studies to supplement the quantitative results.

Action research on few construction projects would be able to find out the critical requirements and constraints to increase the level of applicability. Future research into this topic needs to investigate the elements of cross-organizational culture differences against or towards project learning practices.

ACKNOWLEDGEMENTS

The authors highly appreciate the financial support from the Institute of Research, Management and Consultancy (IPPP), University of Malaya for the research grant provided to conduct the study. Special thanks to all the construction industrial professionals for their valuable contribution to this research.

LESSONS LEARNED PRACTICES: CASE STUDY OF A LEADING IRISH CONSTRUCTION ORGANIZATION

Brian Graham[1] **and Ken Thomas**

Department of Construction and Civil Engineering, Waterford Institute of Technology, Waterford, Republic of Ireland

The implementation of lessons learned (LL) practices within construction organizations are viewed as an important part of knowledge management (KM), having the potential to improve the outcomes of a project. PJ Hegarty & Sons, a leading Irish construction organization, has recently implemented such practices as part of the Engineers Ireland Continuing Professional Development (CPD) accreditation scheme. The purpose of this paper is to identify and evaluate the adopted practices, which include a LL database, supported by LL seminars. Adopting a case study methodology, a survey and in-depth interviews with a broad spectrum of management and professional staff was conducted, including a director, project managers, quantity surveyors, foremen and engineers. It was found that the delivery of LL requires careful consideration of its intended users. In addition to integrating LL practices into existing organizational procedures, notification of new lessons and continuous training on the use of the database are required. Delivery of LL seminars should be focused at project-level and conducted on site to support both individual and organizational learning. The use of both technology and face-to-face interaction is important in the success of LL, particularly in aligning individual learning with that of the organization.

Keywords: case study, construction organization, continuing professional development, knowledge management, lessons learned.

INTRODUCTION

The construction industry is facing numerous challenges; increasing competition, globalization of the construction market, increased demands from clients and society, the impact of new technology, and the requirement to maintain a highly skilled workforce at all levels (Egbu and Robinson 2005). Indeed as a highly knowledge-intensive industry, with specialized expert knowledge and problem solving know-how to the fore, the industry requires a more structured approach to managing knowledge (Egbu and Robinson 2005). Knowledge management (KM) has been promoted as a means of harnessing and utilizing intellectual resources to address these challenges, yet there remains uncertainty about how to devise and implement a viable and cost effective KM initiative in practice (Kamara *et al*. 2002). Embracing the information systems and human resource management strands of discourse, KM is defined from an integrated perspective by Jashapara (2004: 12) as: “the effective learning processes associated with exploration, exploitation and sharing of human knowledge (tacit and explicit) that use appropriate technology and cultural environments to enhance an organization’s intellectual capital and performance.” However, due to its project-based, fragmented and unstable nature, the construction industry is recognized as

[1] bgraham@wit.ie

being poor at learning on a consistent basis and improving performance and is notoriously slow in adapting to progressive change (Orange *et al*. 2003). It is now recognized that there may be much greater potential for KM within individual companies as opposed to temporary project teams (KLICON 1999).

Lessons learned (LL) practices are an important aspect of KM. LL practices refer to "the activities, people and products that support the recording, collection and dissemination of lessons learned in organizations" (Snider *et al*. 2002: 291). The purpose of LL is to capture experiences, successful or otherwise, allowing an organization to avoid repeating costly mistakes, improve future performance and ultimately, the contractor's profit (Carrillo 2005; Kartam 1996). In a study of American contractors, Fisher *et al*. (1998) identified a number of other reasons for implementing a formal LL process as: high staff turnover leading to loss of experience; large size of organizations make sharing knowledge difficult; and departmental silos and fragmentation within the organization. Two key issues were identified by Kartam (1996) in the development of LL practices, a manageable format for organizing, storing, retrieving and updating information and an effective mechanism for collecting, verifying, categorizing and storing information. In devising such practices, Robinson *et al*. (2005) identify two distinct strategies: codification and personalization. Codification involves capturing knowledge in an explicit form and leveraging it using IT tools such as a LL database (LLDB). Personalization focuses on sharing tacit knowledge through human interaction. While a combination of both codification and personalization is most appropriate (Kamara *et al*. 2002; Fisher *et al*. 1998; Voit and Drury 2006), there has been a scarcity of solutions about how to effectively marry social processes with technology (Dixon 2004).

Based on the accepted potential for KM within a construction organization, the objective of the reported research is to identify and evaluate LL practices within a leading Irish construction organization through a case study methodology with the aim of identifying LL practices can be improved.

THE LESSONS LEARNED PROCESS

Fisher *et al*. (1998) developed a LL process comprising the following three stages.

Collection

The identification and capture of a LL is an extremely difficult process, with a variety of tools identified such as post-project reviews and debriefing (Disterer 2002; Kartam 1996). Two approaches have been identified for collection of LL; "a 'sought input' type collection process, where a custodian of the LLP obtains input from various agencies" (Fisher *et al*. 1998: 45) and a requirement for individuals to submit LL themselves (Kartam 1996).

Analysis

A LL must be significant in that it will have a real impact, valid in that it is factually and technically correct and applicable in that it identifies something that eliminates the potential for future failures or reinforces a positive result (Weber and Aha 2002). The analysis of contributed LL is vital considering that "construction practitioners will not accept an assertion that a certain method is superior to another, without a sound rationale" (Kartam 1996: 19). Fisher *et al*. (1998) recommend that analysis of LL be carried out by a team of senior staff with extensive industry experience. In documenting a LL, Kartam (1996) identifies three key components required, a title describing the lesson, information regarding the source and context from which the lessons is collected, and a means for sufficiently classifying the lesson in a manner that allows fast, clear retrieval by multiple parameters.

Implementation

The dissemination of LL can occur by two methods, push and pull. Push methods deliver the LL directly to the user based on their role, interests, training and experience, while pull methods leave the burden of search to the user, who must devote their attention to the source (Weber and Aha 2002). In this context, Weber and Aha (2002: 292) discuss the distribution gap which refers to "the difficulty of transmitting lessons between a lessons learned repository and its prospective user." This can occur for a number of reasons: distribution is not part of organizational processes, users may not know or be reminded of the repository, users may not have the time or skill to retrieve and interpret textual lessons, and subsequently apply the lessons successfully (Weber and Aha 2002). A study by Fong and Yip (2006) identified e-mail or written documents as the most suitable distribution channels for lessons to construction professionals, intranets or websites being the least suitable.

IMPLEMENTING LL PRACTICES

In attempting to implement LL practices and indeed other KM initiatives, a number of challenges have been identified (see Table 1 for LL specific challenges), including poor organizational culture, lack of top management support, lack of dedicated resources such as staff, time and money, and poor ICT infrastructure (Fisher *et al*. 1998; Snider *et al*. 2002; Kartam 1996; Carrillo 2005; Weber and Aha 2002).

Table 1: Challenges in adopting LL practices in construction

Lack of time to capture and use learning experiences
Usually captured at the end of the project when many people have moved on
Loss of insight due to lime lapse between lesson and recording
Failure to uniformly document LL in a useful manner
Lack of proper classification system
Difficulty integrating with existing operations and procedures
Difficulty sharing lessons between experienced and inexperienced individuals
No motivation or perceived benefits for individual employees
Failure to deliver lessons when and where they are needed
Requires people to internalize LL and apply them at work
Difficult to measure and communicate benefits

To improve LL practices, Davidson (2006) advises that the lessons should be regularly reviewed to ensure accuracy, reliability and relevance, incorporate appropriate LL into business processes, training and checklists, educating people to use the LLDB, demonstrate the value in sharing LL and provide positive feedback to contributors and users. Voit and Drury (2006) identify two key aspects of LL programs as influencing program effectiveness, information usefulness and human intermediary activities. Information usefulness is the perceived usefulness of the lesson learned, particularly in relation to an individual's current job responsibilities. To reinforce the importance of the LL program, human intermediaries (e.g. managers) should monitor and review their staff's use of the LL. In order to create an environment conducive to learning, senior management need to visibly support an LL initiative, assess the organization's culture, eliminate barriers, set goals, get departmental buy-in, designate a champion, empower workers, allocate resources, and measure and track results (Robinson *et al*. 2005; Fisher *et al*. 1998).

LINKING LL TO CPD

A central problem of promoting learning across an organization is that despite people acting collectively, they actually learn individually (Kleiner and Roth 1997). Terrell (2000) contends that far from being learned, lessons are at best, observed, particularly in project-based organizations who have found it extremely difficult to capture and reuse the LL (Dixon 2004). In order to move beyond this, Dixon (2004: 18) believes that LL need to be connected to social processes, "the development of relationships, reflective conversations, probing questions and in-depth interactions – that are the backbone of knowledge sharing." In an attempt to address this issue, Turner Construction has devised a knowledge network to develop and train individual employees, aligning learning with the overall business strategy, improving both individual and organizational performance. Adopting a blended learning approach, Turner utilizes its own experiences and knowledge to develop both face-to-face and web-based CPD courses for its staff (Lemons 2005). Training is viewed as an important part of LL practices, in promoting the use and benefits of LL practices and incorporating actual LL into training (Fisher *et al*. 1998; Fong and Yip 2006).

THE IRISH CONSTRUCTION INDUSTRY

Considered "the most important part of Irish economic growth", the overall output of the industry in 2006 was €36bn, accounting for 24% of the country's GNP, with over 12% of the country's workforce directly employed (Davis Langdon PKS 2006: 3). The industry is however, facing a number of challenges: the introduction of fixed price government contracts, an increase in the number of foreign-based firms entering the market, over-reliance on the housing market and a predicted slowdown in construction output in the coming years (DKM 2006). Documented low levels of R&D and innovation in this important industry need to be addressed through improved knowledge transfer and creative thinking (Kelly 2005; CIF 2004). In this regard, the Forum for the Construction Industry, Engineers Ireland and the Construction Information Technology Alliance (CITA) have all cited the strategic importance of KM and its contribution to the knowledge economy.

ENGINEERS IRELAND

Ireland's largest professional body Engineers Ireland (EI) have introduced a CPD accreditation scheme for employers of engineers across a spectrum of industries. Twelve of the top twenty Irish construction companies are currently engaged in the accreditation process, of which three are fully accredited. Specifically defined criteria have been established, against which accreditation of companies is considered: CPD policy, performance management system, CPD activity, recording of CPD, mentoring, involvement with professional institutions, KM system and management control system. It is reasonable to suggest therefore that CPD has an important role to play in KM within construction, at individual, project and organizational levels.

RESEARCH METHODOLOGY

A case study methodology was adopted to evaluate LL practices within PJ Hegarty & Sons (PJH), a leading Irish construction organization. Such an approach was chosen as it seeks a range of different kinds of evidence in a case setting, which when abstracted and collated has the potential to provide the best possible range of answers (Gillham 2000). This study forms part of a wider research project investigating KM in the leading 20 Irish construction organizations as they are perceived to exert the most influence on the approach to managing construction projects and the industry in general (Thomas 1999). Following an interview with a director from PJH in January 2006, the possibility of conducting some in-depth research emerged leading to the design of a questionnaire. Administered between February and April 2006, the purpose of the questionnaire was to explore the effectiveness of identified KM initiatives such as the LL database and seminars, CPD, and communications within the company's Dublin office. Follow-up interviews were then conducted with the full site team on a €70m design and build, commercial development project based in Waterford between May and June 2006.

CASE STUDY RESULTS AND ANALYSIS

Founded in 1925, PJH had a turnover of €320 million in 2006, making them the sixth largest Irish contracting company. Employing in excess of 700 staff, the company undertake a range of large construction projects throughout Ireland from offices located in Dublin, Cork, Limerick and Galway. In 2004, PJH became the first construction company in Ireland to be awarded EI accreditation for CPD.

The questionnaire was distributed to 180 professional and management staff via email, achieving a 36% response rate. As can be seen in Table 2, the survey respondents have a range of experience of working in the construction industry, with over a third having less than five years experience. Conversely, 69% of the respondents have been working with PJH for less than five years. Notwithstanding the 37% with less than five years' industry experience (mostly recent graduates), this may be due to the highly competitive nature of the industry at present, presenting considerable work opportunities to the industry's workforce. Coupled with a relatively young workforce (63% are 35 or under), this low level of experience within the company highlights the need for effective LL practices to improve both the individuals and the organizations knowledge base. The follow-up interviews were conducted with 13 staff members, comprising a senior contracts manager, a project manager, three quantity surveyors, three engineers, four foremen and the site safety advisor all based on site in Waterford.

Table 2: Survey respondents' industry experience

	< 5 years	5–10 years	11–20 years	>20 years	Total
Working in construction	37%	25%	14%	24%	100%
Working for PJH	69%	21%	8%	2%	100%

Overview of lesson learned practices

Based on the initial interview with a director, it was found that PJH had implemented LL practices as part of the KM requirement for CPD accreditation, comprising a LL database (LLDB) and LL seminars. The LLDB is managed by the company's quality and administration manager on a part-time basis. Based in the Dublin office, the LLDB administrator has over 30 years' experience in the construction industry, nine of which have been spent with PJH and is responsible for providing training on the LLDB when new recruits join the company.

The lessons learned process

- *Collection*: chaired by a director, PJH conduct a post-project review for all projects where key members of the project team discuss the best and worst experiences. The loss of experience due to time lapse is addressed by interim review meetings which are held every 6 months and "these would be reviewed as part of the end meeting…it's really at the end of the job that you look back and say 'what are the big issues here?' I mean you can't log everything, if you catch the big issues, you're doing well." In this regard, he added: "at the end of the day our business is building, where do you stop with these initiatives…we try to do our best with the LL, but there's only so much you can do."

- *Analysis*: following the review, the key LL are documented by the contracts manager in a standard template detailing the title, description of the LL and contact details for individuals involved, and is classified based on the trade/subcontract package with which it is associated. Once completed, it is sent to the administrator, and if acceptable it is posted on the database, if not it may be sent back to the source for further clarification or edited by the administrator himself.
- *Implementation*: the archived LL are disseminated via two methods, pull methods occur in the form of a LL database (LLDB), a central repository that can be accessed from all offices and sites by logging into the company's network, the use of which is not measured and tracked by management. The company director acknowledges that "you are depending on people to take the time to look at the database. We also give seminars based on lessons learned on a fairly regular basis to support the database." In conjunction with the HR department, the LL administrator organizes LL seminars based on a selected trade or subcontract packages for staff, and on some occasions delivers them himself. These seminars are usually delivered in the training room of the Dublin office in the evening time.

Evaluation of lessons learned practices

Lessons learned database

According to the director, *"the theory is, and I'd be interested in the answer from your survey on this one, is that before you start a particular package you log onto the database and have a look, in the hope that you don't make the same mistake again."*

Table 3: Frequency of use of LLDB

Rank	Use of LLDB	%
1	Very rarely	34
2	When I have a specific query/problem	27
3	Never	15
4	Quite often	13
5	When a new subcontract package starts	11

Despite nearly three-quarters of the survey respondents (74%) stating that they found it beneficial to them in their work, Table 3 shows that *very rarely* ranked highest in terms of usage, with *when a new subcontract package starts* ranking lowest at 11%. During the interviews, the use of the LLDB was discussed, the following being the most pertinent issues identified:

- *Lack of time*: many respondents stated that they just didn't have the time to look through the database every time a new package started. "I haven't checked it in about a year…you don't get time to, unless you're sitting here twiddling your thumbs…it's extremely difficult when you're out on site all day."
- *Relevance to current role*: some people questioned the actual relevance of LL to them in their current position. One respondent stated "a lot of the things on

the lessons learned are relevant to foreman…they're the guys out there dealing with those issues…that's where the breakdown is, the people who really need to know don't have access to a computer, its not in their job description."

- *No requirement to contribute*: many people stated that there was no requirement on them to contribute to the LLDB, and as a result, didn't bother. One individual suggested "perhaps contributing to the lessons learned should be part of your work. The company I worked for in England did that, when you did your monthly report for the directors, you had to do your lessons learned."
- *Difficulty finding the most recent lessons*: the lessons are not categorized by date, "you have to sift through the older lessons as well." Indeed, 42% of the survey respondents ranked this issue as the most problematic factor in using the database.

In considering how to improve the use of the LLDB, a number of the interviewees contended that there should be refresher courses run, as most people felt that being shown how to use the LLDB on their first day with the company was not effective.

Lessons learned seminars
The LL seminars provided by PJH can count towards CPD hours with a variety of professional bodies, offering incentive for staff to attend. The survey found that 8% of respondents don't attend any seminars, 53% attend between 1 and 4, 31% attend between 5 and 9, with 8% attending 10 or more seminars each year. A number of problems with the seminars were identified in the interviews as:

- *Timing and location of seminars*: the seminars are run in the evening in the Dublin office, after a "hard day's work on site." Many of the interviewees cited fatigue and long travelling times as being counter-productive to getting any value out of the seminars. "We were out working in the rain one day, a big concrete pour…and then I'm into this thing at 5.30…and I mean the heat and all, I'd been out in the fresh air all day, out in the wind, and I come into this nice, cosy, comfortable room to a guy in a shirt and tie…and I'm gone!" One interviewee suggested that "there should be more done on-site, particularly on a big site like this where you have a lot of staff…it's not a thing that has to happen in head office."
- *Delivery of seminars*: "the likes of the office people would be giving a seminar on lessons learned…they talk about them, but because they're not involved on site, they don't come up with any solutions."
- *Relevance*: it is important that seminars are pitched at the right level to the audience "if it's not relevant or you know it already, you're going to switch off," a recurring theme in the interviews, people cited this aspect as putting them off attending again.
- *Experience of attendees*: a graduate engineer felt that they didn't gain a lot from seminars covering issues they hadn't yet encountered on site "once you've seen it been done, I find it's easier to go to a seminar and talk about it…it's hard to visualize something that you've never seen or experienced when you go into a room and listen to someone talk about it for an hour."

DISCUSSION

Based on a case study of LL practices within PJH, this section aims to highlight the strengths and weaknesses of their approach to LL with a view to identifying how construction companies can improve such practices.

The lessons learned process

- *Collection*: a *sought input* collection process is used, whereby the director responsible for the project in question facilitates a post-project review. This end of project review is augmented by interim review meetings during the course of the project and aims to capture the *big issues* related to the project.
- *Analysis*: the LL is analysed and documented on a standard template by the contracts manager, before being sent to the LLDB administrator for further analysis. The documentation of the LL appears to meet Kartam's (1996) recommendations for a title, contextual information and classification, although perhaps the LL should be review by a wider group prior to acceptance as recommended by Fisher *et al*. (1998).
- *Implementation*: both push and pull methods are utilized by PJH in disseminating LL, through seminars and a database respectively.

The process adopted by PJH focuses on capturing the main LL from each of their projects, as the director indicated that it would be difficult to capture all LL from a project. In order to improve this process and capture more LL, further integration with existing organizational practices is required.

Lessons learned database

The use of the LLDB is not monitored by company management, nor are staff required to use it as part of their work, leading to a distribution gap between the database and prospective users. Site-based staff do not dedicate time to using the LLDB as they view their work as being out on site, not at a computer, yet it is precisely these people who should be using it. Finding the most recent LL's were difficult as they were not categorized by date; a more robust classification and search functionality may address this. A simple email system notifying staff in relevant positions of new LL could potentially improve the dissemination of LL. Incorporating the use of the LLDB into company policy, linking use to subcontract awards, and requiring certain key project members to contribute a LL with their monthly reports could improve both collection and implementation of the LLDB.

Lessons learned seminars

To improve the dissemination of LL, CPD seminars are organized in the company office for staff to attend after work. The timing and location of these was found to be problematic for staff who had to travel to the office from site. Furthermore, the people who delivered the seminars were not necessarily those who had actually experienced the lessons learned, thus limiting their knowledge of the context within which the lesson originated. This highlights the problems of actually learning from a documented LL as discussed by Terrell (2000). The experience of people attending the seminars and the relevance of the LL to their work were other issues highlighted as being important. To improve the effectiveness of the seminars, they could be delivered on site to the project team as and when they are relevant. For example, conduct an LL seminar on glazing a week before the glazing subcontractor begins on site with all members of the project team, including foremen.

Linking lessons learned to CPD

The linking of the LL seminars to individual CPD appears to be a step in the right direction, the role of human intermediaries in reinforcing the importance of LL, vital. Collaboration between contracts managers, the HR department and the LLDB administrator, in the delivery of on-site LL seminars as part of CPD activities is required. Further integration of the LLDB and the LL seminars into a blended learning programme may enhance the effectiveness of delivering LL within the organization. In addition, there is now a need for the company to implement a system to track and measure the use and effectiveness of these practices and to communicate benefits throughout the organization.

CONCLUSIONS

The LL practices of a leading Irish construction organization have been identified and evaluated, with a view to making recommendations for other firms considering implementing LL. These practices were investigated in relation to the process used to collect, analyse and implement LL, exploring implementation through a LLDB and LL seminars. Based on this investigation, the following conclusions can be made:

1. Carefully design the LL process and integrate it into existing organizational procedures. The *collection* of LL should incorporate both a sought input and a requirement for individual contributions. Submitted LL should be *analysed* by a number of people, be consistent in their structure and classified by a number of parameters, particularly roles to which the LL is relevant. *Implementation* of LL should combine both push and pull methods, targeting specific staff members through direct distribution.
2. Use of a lessons learned database should be incorporated into existing organizational practices with careful consideration given to the classification system used, particularly based on date of LL. Emails and memos notifying staff of new LL and reminding them to use the database, in addition to refresher courses on the use of the LLDB are also recommended.
3. LL seminars should be organized for staff to augment the LLDB, with careful thought given to the timing, location and delivery of them. Site-based seminars may be more appropriate and relevant on large projects, which can be linked to current and upcoming subcontract and trade packages on site.
4. The integration of LL practices with CPD has the potential to align both individual and organizational objectives. The development of a blended learning approach to delivering and promoting LL merits further investigation, particularly in addressing the need for site-based CPD activities.

While LL practices have the potential to improve the performance of construction organizations, there has been little documented evidence of such improvements in practice. This paper has identified and evaluated LL practices within a leading Irish construction organization, highlighting a number of issues in relation to its implementation that may well be of benefit to other construction organizations in Ireland and overseas.

EVALUATION OF THE BENEFITS OF AN ONLINE CONTRACT CHANGE MANAGEMENT SYSTEM FOR NEC/ECC PROJECTS

Ming Sun[1], Tejas Oza[1] and Robin Wilkin[2]

[1]*Faculty of the Built Environment, University of the West of England, Coldharbour Lane, Bristol, BS16 1QY, UK*

[2]*Management Process Systems Ltd, 4 The Lanterns, Melbourn Street, Royston, Hertfordshire, SG8 7BX, UK*

The Contract Change Management (CCM) system is an online service, purpose-designed to support the project management processes of the NEC/ECC (New Engineering Contract/Engineering and Construction Contract) form of contract. Anecdotal evidence suggests that the system helps projects reduce risks and save costs. This study seeks to ascertain the key benefits of CCM from the user perspective, through a questionnaire survey. A questionnaire was sent to 260 randomly selected CCM users and 85 (33%) valid replies were received. The results showed that there is a high degree of consensus of the benefits of the CCM system in eight key project management aspects: process improvement; business improvement; risk management; communication; management information; efficiency; collaboration/partnering; and traceability. However, there are also some different opinions on what the most important benefits of the system are from different groups of users, i.e. clients, contractors and consultants.

Keywords: contract management, information technology, partnering, project management, statistical analysis.

INTRODUCTION

Traditionally, project changes and variations often cause disputes, claims, delays and cost overruns in the construction industry (Arain and Pheng 2005; Ibbs 1997; Love and Li 2000). Changes can be caused by a variety of factors, such as site conditions, climate, design changes, client requirement changes, communication failures, poor site management, external conditions, etc. Some of these factors are beyond the control of the project team. All they can do is to be prepared for the inevitable changes in order to minimize any negative impact. In most cases, the earlier a potential change is identified the easier it can be dealt with. The NEC/ECC contract (Mitchell and Trebes 2005), initially published in March 1993, seeks to address project change management through encouraging good management process and better collaboration between all parties involved in the decision making process. NEC/ECC requires the principal parties to notify each other as soon as certain conditions become apparent, which may lead to project changes at a later stage. This is called an Early Warning (EW) because it allows the team time to consider their options to deal with the risk, before it impacts on the project's timescales, costs, safety, or quality. During NEC/ECC projects, the team is required to hold regular EW (also known as risk

[1] ming.sun@uwe.ac.uk

reduction) meetings to review all known risks and consider action. When a change risk is identified, the project manager (PM) usually needs to issue an instruction to the contractor to deal with the risk or carry out necessary change. If the change has an impact on cost and/or schedule, it will be regarded as a “compensation event”. The contractor is then required to provide a quotation for the work, including costs for any time-related works caused by any delays. The response period for this is usually three weeks, although this may be extended. The PM then has two weeks to accept the quotation, seek resubmission due to incorrect assessment, or carry out a PM assessment. The quotation value is then implemented or added to the total price, or target cost in some cases. In most projects, the commercial and programme impact of a PM instruction (PMI) is usually considered and partially agreed at the EW meeting.

Although the process of change management under NEC/ECC is well defined, its successful execution in practice relies on good communication and information sharing between the parties, as well as robust support for the decision making process. These are difficult to be achieved without the support of an appropriate tool. The Contract Change Management (CCM) system is an online application specifically designed to support the change management process for projects that adopt the NEC/ECC form of contract. The system manages the life cycles of all notices issued by the NEC/ECC contract, in a collaborative environment over the Internet. These include EW, PMIs, notification of compensation events (CE), quotations, PM assessments, implementations, and a variety of PM/contractor communications. All documents are user and date stamped and held in an audit trail. The impacts of CEs are monitored against the activity schedules for each work package, in order to ensure that the adjusted target price and target completion date are up to date. The system is available to all registered users over the web, and is password protected. The key business improvement benefits of CCM include: (1) increased productivity by improving communication efficiency; (2) improved predictability of outcome (cost & time); (3) reduced project risk; (4) better compliance with contract requirement; and (5) process visibility and auditability.

During the last few years, the CCM system has been used by a growing number of companies in the UK. Many users are convinced of the benefits of CCM in helping them reduce risks and save costs based on anecdotal evidence. There is a desire by both the CCM service provider and its users to ascertain the benefits of the system through a user survey. The aim is to establish: (1) does the system deliver the benefits it promises in practice; (2) what are the most important benefits from the user perspective; and (3) are there any differences between different user groups?

QUESTIONNAIRE SURVEY

In recent years, there is a growing interest in the evaluation of IT benefits in construction. Numerous evaluation frameworks have been proposed by CIRIA (1996), Construct IT (1998), Li (1996), Marsh (2000), etc. However, empirical studies of IT benefits in practice are rather limited. Stewart (2003) reported a user survey study aimed at evaluating the value of IT adds to the process of project information management in construction. A similar study was conducted by Love (2005). Both authors recommended questionnaire survey as a useful instruction for such a study.

The study also adopted the questionnaire survey approach. A questionnaire was developed, which contains questions in five sections:

- Profiles of the respondents and their organizations.

- Respondents experience with NEC/ECC contract and the CCM system
- Evaluation of the benefits of CCM.
- Evaluation of functional aspects of CCM system.
- Evaluation of the quality of the service provider.

Details of the questions will be explained in the following analysis of survey results. A total of 260 users were randomly selected from the existing CCM user database. A pilot study was carried out with five selected users. As a result, some minor adjustments were made to some of the questions before the questionnaire was sent out. However the changes are not significant. Therefore, the five responses of the pilot were included with 80 responses received during the main survey. This makes the total number of valid responses 85, representing a return rate of 33%.

ANALYSIS OF SURVEY RESULTS

Profiles of respondents

- The responses to the survey included Main Contractors (40%), Client Organizations (21%), Consultant Quantity Surveyors (15%), Project Management Consultants (14%) Architect/Design/Engineering (5%), and Specialist Sub Contractors (1%), as well as ‘Others’ (4%).
- According to disciplines, the responded group included Project/Contract Managers (41%), Quantity Surveyors (19%), Directors/ Senior Managers (15%), Commercial Managers (11%), Supervisors/ Clerk of Works (4%), Architect/ Design/ Engineering (1%) and ‘Others’ category (9%).
- Almost all respondents have broadband Internet access: 92% of respondents have Internet access at work; 46% can access using laptop; 62% have home Internet access; and 27% use Internet from other business offices.
- Approximately 31% of respondents have over 25 years of experience in the construction industry, another 31% have 16–25 years and 32% have 6–15 years. A small number (under 7%) have 0–5 years of experience. (or 94% of respondents have more than six years experience in the industry)
- Most of the respondents have used the NEC/ECC form of contract. Amongst them, 24% have used NEC/ECC on over six projects; 29% have used it on 4–6 projects and 44% have used NEC/ECC on 1–3 projects.
- 94% of the respondents have used CCM on their projects. The number of projects on which they used the system varies. CCM supports two types of users: Active User (who can enter information into the system) and Read Only User (who can only read and download information from the system); 74% of the CCM users surveyed were Active Users (they might also be Read Only users on different projects) and 26% are Read Only users.
- 12% of the respondents are using CCM at Initial stage of their project; 35% at Mid stage; and 29% at the End/Closure stage – 19% are not currently using the system.
- 30% of all respondents use CCM up to an hour per week; 35% use it for 1–3 hours; 25% use for 3–5 hours; 5% use 5–8 hours and 5% use it for more than eight hours per week. However, the usage varies between client, contractor and consultant users, as well as between different project stages.

Respondents' views on the benefits of CCM

Prior to the survey, a list of 43 potential benefits was identified based on anecdotal evidence. These benefits were included in the questionnaire under eight categories: (1) Process improvement; (2) business improvement; (3) risk management; (4) communication; (5) management information; (6) efficiency; (7) collaboration/partnering; and (8) traceability. The respondents were asked to rate each benefit. The question in the questionnaire reads: "anecdotal evidence indicates CCM offers the following benefits. Do you agree?" For each benefit, the respondents were asked to click one of four possible answers: "Strongly agree", "Agree", "Disagree" or "Strongly disagree". Respondents were asked to answer as many questions as they can, if they could not answer all of them. In the following analysis, a numeric score is assigned to each answer: Strongly agree – 4, Agree – 3, Disagree – 2, and Strongly disagree – 1.

Tables 1–8 show the results of the benefits survey. In each table, the percentage of responses for each answer is shown together with a mean score and standard deviation value for every benefit. For example, Table 1 shows the results for the benefits related to process improvement. For the benefit "1.1 Quality assured change management process", 2% of the respondents answered "Strongly disagree", 9% of them answered "Disagree", 65% answered "Agree" and 24% answered "Strongly agree". This gives this benefit a mean score of 3.11 and standard deviation of 0.65. Under this scoring scheme, the minimum value is 1, which represents 100% "Strongly disagree" with the existence of that benefit. Maximum value is 4, representing 100% "Strongly agree". The median value is 2.5. Any mean score greater than 2.5 represents a positive feedback.

Table 1: Benefits of process improvement

Benefits	(1)	(2)	(3)	(4)	Mean	SD
1.1 Quality assured change management process	2%	9%	65%	24%	3.11	0.65
1.2 Rigorous process for management of change	1%	7%	66%	26%	3.16	0.60
1.3 IT support ensures the automated flow of work (workflow) against an agreed baseline and organization structure	3%	19%	65%	13%	2.88	0.64

Table 2: Benefits of business improvement

Benefits	(1)	(2)	(3)	(4)	Mean	SD
2.1 Reduce cost of implementing ECC	6%	38%	44%	12%	2.61	0.78
2.2 Reduce number and scale of disputes	6%	35%	50%	9%	2.62	0.74
2.3 Quicker closing of final accounts	8%	24%	46%	22%	2.83	0.87

Table 1 shows the results of three benefits related to CCM's assistance to the quality of the change management process. They indicate a consensus on the benefits in helping with the process of contract change management. For benefits 1.1 and 1.2, around 90% of the users responded positively. The replies from the client group are 100% "Agree" or "Strongly Agree" on these two benefits. The support for workflow automation (benefit 1.3) is recognized by 78% of the users.

Table 2 are results on the business improvement benefits. Although for all three benefits in this category the majority of the respondents answered "Agree" or "Strongly Agree", the results are less than overwhelmingly conclusive. It shows that IT can only provide the potential for business improvement. To realize the potential, corresponding changes in process, people and culture are required. Furthermore, it also illustrates the difficult in quantifying the impact IT tools in construction projects.

Table 3: Benefits of risk management

Benefits	(1)	(2)	(3)	(4)	Mean	SD
3.1 Greater visibility of status of all incidents	1%	11%	63%	25%	3.11	0.63
3.2 Provides a complete and documented audit trail	1%	2%	51%	46%	3.41	0.61
3.3 Provides early warning notification of risk	0%	11%	57%	32%	3.21	0.63
3.4 Rapid resolution of disagreements	6%	45%	44%	5%	2.45	0.68
3.5 Quicker agreement of compensation events	8%	30%	59%	3%	2.57	0.67
3.6 Focuses effort on proactive management of early warnings	1%	16%	65%	18%	2.99	0.63
3.7 Improves compliance to ECC procedures and contract management requirements	1%	6%	63%	30%	3.21	0.61
3.8 Reduces risks of implementing ECC	4%	18%	63%	14%	2.88	0.69

Table 3 shows the survey results of benefits related to risk management. In this category, the results showed a very big variation. For benefit 3.2, the percentage of “Strongly Agree” and “Agree” answers is 97%. However, for benefit 3.4 this percentage is only 49%. This is one of the only two benefits in this survey, which received less than half positive responses. This negative feedback of 3.4 shows the limited role that tools such as CCM can play after a disagreement occurs. However, tools can help to prevent some disagreements from happening in the first place, as indicated by the result for benefit 3.5. Another contributory factor for the low score for 3.4 may be the wording of the question. Even if CCM can play a role in resolving disagreement, its impact would not necessarily lead to ‘rapid’ resolution. Nevertheless, the general positive responses for most of the benefits, especially related to the implementation of NEC/ECC (3.1, 3.3, 3.7, 3.8), show that CCM users value the system in reducing process related risks of managing NEC/ECC projects.

Good communication is essential for both avoiding unnecessary changes and managing necessary ones effectively. Up to 91% of the CCM users agree with the benefits of the system in supporting and recording all communications related to each change event (4.3 and 4.7 in Table 4). The greater transparency provided by the system, especially from client’s and senior manager’s perspectives (4.4 and 4.6), is also recognized. Furthermore, the system also provides a central repository for all documents related to management of contract changes. As a result, the majority of the users believe that CCM helps to improve the communication between all the parties (4.1).

Table 4: Benefits of communication

Benefits	(1)	(2)	(3)	(4)	Mean	SD
4.1 Improves communication between all parties	5%	21%	60%	14%	2.84	0.73
4.2 Documents are not lost or mislaid – leading to a reduction in authentication queries.	0%	7%	60%	33%	3.27	0.57
4.3 Provides e-mail notification for important actions	4%	10%	60%	26%	3.09	0.71
4.4 Facilitates monitoring of the project by senior management	1%	9%	74%	16%	3.05	0.55
4.5 Instant availability of latest adjusted contract (target) price	4%	12%	64%	20%	3.00	0.69
4.6 Visibility to the client about changes in the project (usually price)	1%	6%	73%	2%	3.11	0.55
4.7 Records communications through PMI, EW, CE, NCE etc., thus reduces risk of unknown change	0%	9%	62%	29%	3.20	0.58
4.8 Use of CCM database as a master document for decision making and checking project status	3%	29%	57%	11%	2.76	0.68
4.9 Awareness of cost issues by all parties	4%	25%	55%	16%	2.84	0.74

Table 5: Benefits of management information

Benefits	(1)	(2)	(3)	(4)	Mean	SD
5.1 Data gathered can be analysed during and after the contract	3%	6%	71%	20%	3.09	0.60
5.2 Recording of contract progress with date stamps for easy retrieval and analysis	1%	8%	71%	20%	3.09	0.57
5.3 Provides online contract performance information	1%	18%	66%	14%	2.93	0.62
5.4 Provides data export facilities for key performance trend management	3%	23%	71%	3%	2.74	0.56
5.5 Improved predictability of end costs and end dates	4%	36%	51%	9%	2.66	0.70

Similarly, the feedback on benefits of management information is largely very positive (Table 5). One exception is "5.5 Improved predictability of end costs and end dates". A sizable minority (40%) of users did not agree with this benefit statement. The reason for this will be investigated in the next phase of research.

Table 6: Benefits of efficiency

Benefits	(1)	(2)	(3)	(4)	Mean	SD
6.1 Simple, point and click operation of the entire process	1%	16%	68%	15%	2.97	0.60
6.2 Minimizes administrative and secretarial activities	5%	23%	53%	19%	2.86	0.78
6.3 Version and authorization control of documents, minimizes disagreements over facts	1%	23%	58%	18%	2.93	0.68
6.4 Reduces QS time and costs, as CE are agreed quickly	9%	46%	33%	12%	2.47	0.82
6.5 Reduces QS costs due to reduction in unresolved issues post completion	8%	32%	51%	9%	2.62	0.77
6.6 Reduces post project completion issues	6%	24%	54%	17%	2.82	0.78
6.7 Improves quality of quotation, build up information and related audit trail	9%	27%	48%	16%	2.71	0.85
6.8 Saves man hours in document creation, filing and searching	6%	17%	51%	26%	2.96	0.83
6.9 User friendly software – reduces induction timescales	8%	12%	68%	12%	2.83	0.73

Table 6 shows the survey results for efficiency benefits. For benefits of efficiency about the operation of CCM system itself (6.1, 6.9), the answers were very clear-cut and positive, with 83% and 80% positive responses. For benefits of efficiency about project management, the answers were more mixed (6.2, 6.4, 6.5 and 6.6). Indeed, for "6.4 Reduces QS (Quantity Surveyor) time and costs, as CE agree quickly", over half (55%) of the respondents did not agree.

Table 7: Benefits of collaboration/partnering

Benefits	(1)	(2)	(3)	(4)	Mean	SD
7.1 Provides access to process operation and status information by all parties, any time, any place	0%	3%	75%	23%	3.20	0.46
7.2 Assures document version control through a secure audit trail	0%	6%	70%	23%	3.17	0.52
7.3 Facilitates collaborative decision making	1%	26%	63%	10%	2.82	0.62
7.4 Highlights next action which cannot be ignored or forgotten	0%	10%	66%	24%	3.14	0.57

Table 8: Benefits of traceability

Benefits	(1)	(2)	(3)	(4)	Mean	SD
8.1 Archives of key documents for analysis at any time	1%	8%	66%	25%	3.15	0.60
8.2 Date stamps all key operations	0%	1%	65%	34%	3.33	0.50

Collaboration and partnering underlie the core principle of NEC/ECC. CCM is designed to support this principle. The responses to the survey in this regard, shown in Table 7, confirmed that CCM benefits the promotion of collaboration between project partners. The positive answers for three out of four benefits in this categories are over 90%.

The main function of CCM is to support the key processes of NEC/ECC with regards to contract change management. The system keeps a record of the whole decision making process, which can be easily reviewed at a later stage. It is therefore not surprising to find that benefits of traceability received the highest rating (Table 8).

The ranking order of the categories of benefits was analysed according to the average percentage of positive replies (“Agree” and “Strong agree”). Traceability tops the list with 95%. It is followed by collaboration/partnering (89%), process improvement (86%), communication (84%), management information (79%), efficiency (70%) and finally business improvement (61%).

The rating for each benefit in Tables 1–8 is based on respondents’ assessment of that benefit independently. It is an indication of how well CCM helped to achieve that particular benefit. However, it does not imply the degree of importance of that aspect. In order to find out what are most important from the users point of view, respondents were asked to list top five benefits in an order of importance. During analysis, a weighing factor was assigned to different score, 100 to first benefit, 95 to second, 90 to third, 85 to fourth, and 80 to fifth. Then, the accumulative score is calculated for each benefit and a ranking is decided based on the final score. The benefit with the highest score ranks first, next highest score ranks second, and so on. The result, based on ranking from all respondents, is shown in column 2 of Table 9. The same analysis was also done for different groups of respondents separately. The results are shown in columns 3–5 of Table 9. It is interesting to note the difference in the ranking by different groups. For example, “3.7 Improves compliance to NEC/ECC procedures and contract management requirements” was ranked top by all respondents as a whole group. It was ranked top by clients and consultants in the organization category and by director/commercial managers and designer/engineers in the role category. However, it was only ranked fourth by contractors (in organization category) and seventh by project manager/contractor managers (in the role category). “1.2 Rigorous process for management of change” was ranked third overall, but did not even make the top 10 in the contractor’s ranking.

Table 9: Ranking of top 10 benefits

	Ranking by all	Ranking by clients	Ranking by contractors	Ranking by consultants	Ranking by PM/CM	Ranking by director/commercial managers	Ranking by designers/engineers
3.7 Improves compliance to ECC procedures and contract management requirements	1	1	4	1	7	1	1
3.2 Provides a complete and documented audit trail	2	4	7	2	1	-	2
1.2 Rigorous process for management of change	3	3	-	4	3	7	5
4.7 Records communications through PMI, EW, CE, NCE etc., thus reduces risk of unknown change	4	-	-	6	6	-	3
2.3 Quicker closing of final accounts	5	6	-	10	4	-	6
7.4 Highlights next action which cannot be ignored or forgotten	6	-	1	-	2	6	-
3.6 Focuses effort on proactive management of early warnings	7	-	-	5	5	-	-
7.1 Provides access to process operation and status information by all parties, any time, any place	8	-	-	3	8	-	7
3.3 Provides early warning notification of risk	9	-	2		-	2	-
3.1 Greater visibility of status of all incidents	10	-	3	10	-	8	8

Table 10: Estimations of financial value of CCM's benefits

Value of benefits (£)	**No of replies**
<5,000	6
5,000–10,000	3
10,000–50,000	4
50,000–100,000	4
>100,000	2
Average: £74,474	Total: 19

Risk management is clearly regarded as the most important issue. Five of the top ten benefits in Table 9 are related to risk management. When users were asked to identify top five benefits, they were also asked to indicate whether each identified benefit is related to "Reduction of Risk", "Reduction of Cost", or "Reduction of both Risk and Cost": 43% of the identified top benefits are regarded as related to "Reduction of Risk", 15% are related to "Reduction of Cost", and 43% are related to "Reduction of both Risk and Cost". Because some users ticked more than one box, the total percentage is over 100%.

The survey asked CCM users to quantify, if possible, the value of the benefits arising from using the system in their projects; 19 out of 85 respondents answered this question. The results are shown in Table 10.

It is widely acknowledged that the benefits of an IT system are often difficult to quantify in monetary terms. Any real savings are dependent on many factors, such as size of the project, competence of the project team, external context, etc. The IT system can only play a part, sometimes maybe an important part, in delivering business benefits. The figures in Table 10 are respondents' subjective estimates. The background contexts need to be investigated in detail before solid conclusions can be made.

Finally, 84% of users of the survey regarded CCM as a 'Good' or 'Excellent' system; and 92% of the users are happy with the quality of service by the service provider.

CONCLUSIONS

The questionnaire survey results were previously reported in an interim research report (Sun 2006). New in-depth analyses have been presented in this paper.

The results of the CCM user survey have proved users' appreciation of the benefits that the system provides during contract change management process of NEC/ECC projects. Overall, the users' responses are very positive and consistent: 41 or 43 benefits received positive feedback with a mean score higher than the median value. The standard deviations for most mean scores are relatively small. Process supports, such as audit trail and communication records, received the highest percentage of positive replies. The answers to benefits related to cost saving and business improvement are more mixed. Although there is a degree of consensus on the benefits that the CCM system is providing, there are considerable differences between different organizations and roles on what the most important benefits are.

TECHNOLOGICAL READINESS FOR WIDESPREAD USE OF E-COMMERCE IN CONSTRUCTION

Ihab Ismail[1] and Vineet Kamat

Department of Civil and Environmental Engineering, University of Michigan, Ann Arbor, MI, USA

This paper discusses e-construction infrastructure, its definition, importance and status, and recommendations for its improvement. This paper builds on the current existing research in e-construction and offers recommendations for restructuring e-construction by focusing first on the infrastructure as the first building block. The paper will summarize the challenges in e-construction while focusing on providing a framework to overcome those challenges. The paper starts by defining the e-construction infrastructure, then presents an argument for why we should investigate e-construction infrastructure. It then proceeds to summarizing the status of e-construction infrastructure, and provides a framework for improvement. The e-construction infrastructure is interdisciplinary in nature; it involves business process, trading models, network hardware and software infrastructure, software interoperability standards, legal standards, and more. Therefore, an interdisciplinary approach is used in building or improving this infrastructure. The thesis of this paper is that the ultimate value that the industry can derive from e-construction will be reached when those disciplines and standards are aligned in an integrated e-construction infrastructure.

Keywords: contracting, information management, information technology, modelling, standardization.

INTRODUCTION

The successful execution of a project requires preplanning – a phase known in the architectural, engineering and construction (AEC) industry as preconstruction. This is well known and widely practiced in the construction industry (Anonymous 2005c). Contractors plan their projects before they bid or attempt to execute them. It is surprising then to see why the construction industry embarked on a long journey, one that was indeed needed, of IT investments with little or no pre-planning. The lure of first to market advantages, large volume of transactions, and prospects of high market share have sparked a rat race for investment in information Technology (IT) and electronic construction (e-construction). It has been estimated that US$2.5 billion was spent in capital investments by Application Service Providers creating Project Management and collaboration portals alone (Nitithamyong and Skibniewski 2004). It is naïve to expect that by investing in IT alone, the construction industry will adapt naturally to the new infrastructure and the business processes will change to accommodate the change. Dramatic improvement in industry performance requires equally dramatic changes to business processes and management practices, and, more importantly, a strong infrastructure to support these changes (Severance and Passino 2002). It comes as no surprise that the productivity for many AEC companies have been flat or declined over the past five years despite of all the IT investments completed in the same period (Anonymous 2005c)

This paper is part of ongoing research at the University of Michigan that aims at analysing the status of e-commerce in the construction industry, the e-commerce infrastructure, identifying impediments and challenges, and research solutions for the identified challenges. As the topic is multidisciplinary in nature, the research is also multidisciplinary covering knowledge in computer science, construction engineering and management, business, and legal aspects; it involves business process, trading models, network hardware and software infrastructure, software interoperability standards, legal standards, and more. To approach this multidisciplinary problem, a framework was identified for analysing and managing e-construction barriers and challenges. The research grouped the challenges under four focus areas: technological, risk management, managerial and organizational, and information liquidity. The thesis of this paper is that the ultimate value that the industry can derive from e-construction will be reached when those disciplines and standards are aligned in an integrated e-construction infrastructure.

This paper is the second in a series of papers discussing each of the focus areas. The first paper focused on legal risks analysis for e-construction (Ismail and Kamat 2005). The focus in this paper will be on discussing the e-construction infrastructure, its importance, status and recommendations for its improvement. This paper builds on the current existing research in e-construction and offers recommendations for restructuring e-construction by focusing first on the infrastructure as the first building block. The paper will summarize the challenges in e-construction while focusing on providing a framework to overcome those challenges. The paper starts by defining the e-construction infrastructure, then presents an argument for why we should investigate e-construction infrastructure. It then proceeds to summarizing the status of e-construction infrastructure, and provides a framework for improvement.

E-CONSTRUCTION INFRASTRUCTURE

The e-commerce infrastructure is defined here as the supporting capabilities for online trading between multiple companies which includes hardware, software, networks, online payment technologies, security and encryption technologies, online trading business models, and legal and regulatory framework. This can be broken down into the following four groups of components:

- Technology aspects. Hardware, software, networking protocols, encryption technology, online payment technology, etc.
- Business aspects. Business models (Business to Business (B2B), Business to Consumer (B2C), Consumer to Consumer (C2C)), Internet-enabled business processes, supply-chain integration capabilities, information liquidity, etc.
- Legal and regulatory aspects. Legal requirements for e-commerce, regulations for electronic trading, electronic signature act, etc.
- Information Liquidity and Knowledge Management. Level of information liquidity and common across-industry taxonomy are critical for deriving more value from e-commerce markets.

Users can often be included as the fifth category. One can argue that users are one of the most important supporting capabilities for online trading, and often is the case that they are one of the most important challenges as in the construction industry.

Figure 1 illustrates an e-construction marketplace technology infrastructure. It shows buyers and seller with different connection configuration (single computer access, multiple computer access, and multiple computers, multiple location networked access.) Buyers and sellers can connect to the e-construction marketplace through the Internet. The Internet connections could be established by connecting to the Internet Service Provider (ISP) through dial-up, digital subscriber line (DSLs), T1, T4 or other link types. The e-construction configuration (e-construction marketplace versus single point buyer B2B e-commerce, single point seller B2B or B2C e-commerce) represents the business aspect. The third aspect is represented through the legal and regulatory framework within which these online trading activities operate, and the fourth aspect represents that market information that flows between different network nodes.

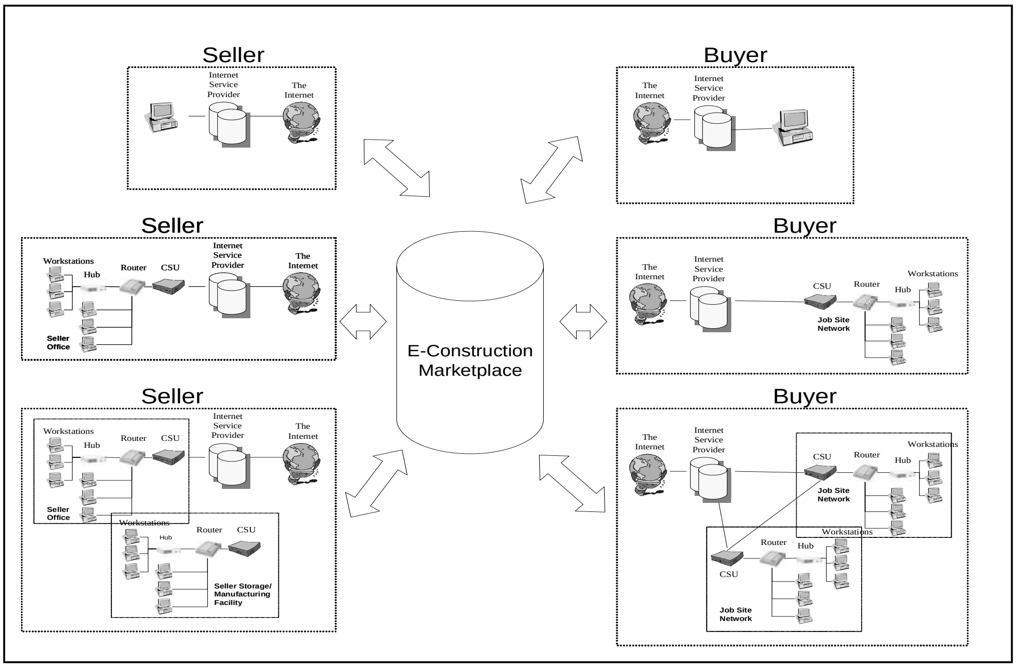

Figure 1: E-construction marketplace infrastructure model

WHY INVESTIGATE E-CONSTRUCTION INFRASTRUCTURE

The value of e-commerce increases exponentially in proportion to the number of users. This is stated in the literature in different variations. Metcalfe's law states that "the value of a network increases by the square of the number of people or things connected to it", and Kelly's law of networks states that "in online exchanges, where multiple buyers and multiple sellers come together in a virtual trading space, the potential value of a neutral B2B exchange is thus nn, where n is the number of users connected to that exchange" (Sculley and Woods 2001). This is better explained by using e-bay as an example. E-bay is a Customer-to-Customer (C2C) electronic marketplace which creates many market efficiencies such as easier search tools, better pricing mechanisms derived through auctioning, and an online reputation tracking system; however, the core value of e-bay is its ability to connect more buyers to more sellers than in conventional markets. Gaining critical mass in a market segment is key for success in order to deliver value to participants. Figure 2 shows that the growth of Gross Merchandise Sales on e-bay mimics closely the growth pattern of the number of e-bay users and that both are of exponential nature (source numbers are taken from E-bay Annual Report) (E-Bay 2003).

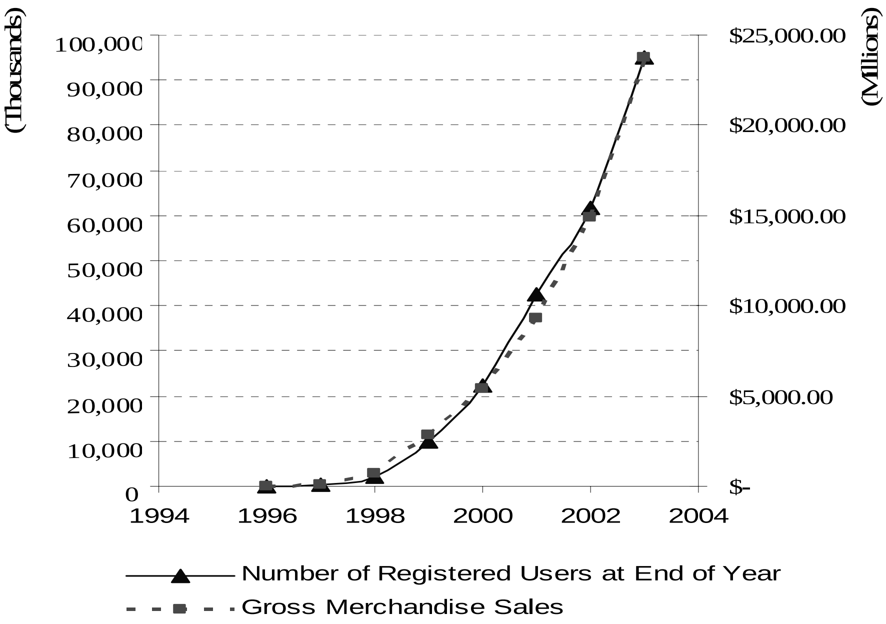

Figure 2: Growth of E-Bay users and gross merchandise sales

Kelly's law applies to e-construction in a similar manner. E-construction is similarly undergoing a process of exponential growth caused by a rapid evolution of the value of e-construction coupled with decreasing barriers of entry. This process will drive more members of the AEC industry to join the e-commerce network putting more pressure on the current e-construction infrastructure. It is important then to analyse what is needed to strengthen this infrastructure in the next phase and to allow for higher returns on e-construction investments.

This trend has been identified in the literature for e-construction. The tipping point estimated between 2004 and 2005 (Nitithamyong and Skibniewski 2004; Unger 2002) and occurs when the online e-construction solutions mature enough to stabilize and reduce the cost of participation to be justifiable for small and medium enterprises. Additionally, a survey conducted by *Engineering News Records* (ENR) estimates the number of AEC firms using e-construction tools to double every six months (Nitithamyong and Skibniewski 2004).

SUMMARY AND STATUS OF E-CONSTRUCTION CHALLENGES

The construction industry in the US in particular, and in many other developed countries in general, recognized the successes and challenges of e-construction. There are a magnitude of reports in the literature about e-construction; many about the challenges of e-construction. Perhaps the most comprehensive is the Construction Industry Institute research on e-construction (Veeramani *et al*. 2002). There are many additional resources that discuss web based project management and survey user view points (Nitithamyong and Skibniewski 2004; Mohamed and Stewart 2003; Stewart and Mohamed 2004; Love *et al*. 2004). The following is a summary of the key challenges facing e-construction grouped and organized within the framework developed under this research. The summary is adapted from the literature (Nitithamyong and Skibniewski 2004; Veeramani *et al*. 2002; Gallaher *et al*. 2004) and expanded upon based on the current research findings.

Technological challenges

Perhaps the one area that is investigated heavily in e-construction relates to the technology (Nitithamyong and Skibniewski 2004). There are several challenges related to the technological aspects of the e-construction infrastructure. These are: interoperability, security, in-adequate software, connectivity, and reliability.

The problem of interoperability arises when there is a many-to-many trading relationship. When each supplier is dealing with few buyers, or each buyer is dealing with few suppliers, preset exchange protocols can be established alleviating interoperability issues. Interoperability is a major concern in all aspects of e-construction. The cost of interoperability is one of the major challenges to wide implementation of e-construction (Veeramani et al. 2002). Suppliers are faced with the dilemma of having to adapt to all their client online trading needs while still catering to their own internal standards (Gallaher *et al*. 2004). Several groups, such as International Alliance for Interoperability (IAI) (Anonymous 2005b) and FIATECH – an industry led, collaborative, not-for-profit R&D Consortium (Anonymous) – are currently working on solutions for this issue.

Security is also a major concern for e-construction applications (Nitithamyong and Skibniewski 2004; Veeramani *et al*. 2002; Alshawi and Ingirige 2003; Berning 2003). So far, most e-construction applications are using user passwords as the single attribute authentication system. As the industry moves to exchanging more important information online, the single attribute system will not be adequate. One can also establish that it is not adequate for the current use of project management and collaboration, but most certainly, it is less adequate for legally enforceable electronic contracts or documents with legal consequences.

The fragmentation of the software features and lack of enterprise-wide solutions is yet another one of the key reasons for the industry's inability to fully utilize the e-construction environment to boost its productivity (Veeramani *et al*. 2002; Alshawi and Ingirige 2003; Berning 2003). Several surveys have indicated that users are looking forward for an enterprise-wide solution instead of the stand-alone software for each business task (e.g. scheduling, estimating and collaboration) that is currently in use (Veeramani *et al*. 2002; Anonymous 2005a).

Connectivity and reliability are closely related although different challenges. Connectivity relates to the number of business entities that are connected to a network. As illustrated earlier in this paper, the network value increases rapidly with the increase in the number of connected users. The fact that many construction sites are located miles away from the nearest connection point for a T1, DSL or broadband connection could present a challenge (Fischbach 2002).

A recent report stressed the increasing costs of maintaining network availability with the added impact of voice data additions, weaknesses in the U.S. power grid, and increased equipment density (Anonymous 2004). The report also indicated that availability goals are increasing for all network providers (Anonymous 2004). It is important to note that reliability for online e-construction application depends on many factors other than establishing redundancy and reliability at the application server side. The network is usually as reliable as its weakest link is. If contractors do not utilize an Uninterrupted Power Supplies (UPS) system, they risk connection failures because of power outages even though they subscribe to a network provider than have redundant UPSs system in place on their server side. Power failures are only but one cause of network failure. Human error has been identified as the highest of any factors causing network failure, followed by viruses, hardware failure, software failure and power failure, consecutively (Anonymous 2004). Reliability will become more important as e-construction crosses the casual exchange of documents online, to the more time-sensitive e-procurement arena. Contractors will want to ensure that their network will not fail when they are in the process of submitting their time-sensitive bids online. Bid recipients on the other side will also want to ensure their systems can handle the high-traffic required at bid submission times (Berning 2003). Reliability can also surface in different forms than the previously discussed: reliability of the service provider or online market-maker to remain in business. BuildNet is an example for this challenge. BuildNet filed for bankruptcy and their customers had to switch to other systems when their contracts were bough by BuildNet's competitors as part of the bankruptcy settlement (Berning 2003).

Legal challenges

The legal challenges are the least investigated as it relates to e-construction. Legal issues are extremely relevant and important to any e-construction effort. The size and complexity of transactions present the key difference between e-construction and buying a book at Amazon.com, for example. Legal challenges was investigated in more detail in this research and published in another paper (Ismail and Kamat 2005). The key legal issues are agency, jurisdiction, contract formation, validity and errors, authentication, attribution and non-repudiation, and privacy concerns.

The most difficult legal challenge in e-construction is posed by intelligent software agents. Software agents are computer programs capable of learning and taking decisions on behalf of their owners (Dzeng and Lin 2004; Ren and Anumba 2004). They take decisions themselves instead of supporting users in making decisions (Ren and Anumba 2004; Schoop *et al*. 2003). Several software agents are developed, or currently in development, that target the construction industry (Dzeng and Lin 2004; Ren and Anumba 2004; Anumba *et al*. 2003; Tah). Intelligent agents pose serious legal challenges to the current legal system primarily in the area of contracting and agency laws. The basic question is whether intelligent agents could have a separate legal personality from their owner or not? The law will not necessarily accept the capability of agents to take actions on behalf of owners as legal consent from the owners to bind them contractually (Bain and Subirana 2003).

Jurisdiction issues pose the next challenge to e-construction. Electronic contracts have no geographical boundaries. Laws and regulations, in contrast, do have geographical boundaries. This basic decision of which court has jurisdiction over a dispute is challenged by these contradictions. This challenge often exists in areas like intellectual property rights. Determining jurisdiction for intellectual property rights is important for distribution of drawings and project documents online in e-procurement systems.

A contract is a promise for a promise (Fuller and Eisenberg 2001). The promises are usually exchanged as an offer and acceptance of the offer. In e-construction transaction, however, it may not be easy to distinguish the offeror from the offeree. This threatens the essence of the contract for a contract is not formed unless the offer is accepted by the oferee.

Authentication, attribution and non-repudiation are yet another set of concerns for e-construction. Attributing an electronic message or agreement to an e-contract to the person who purports to send is critical to the success of e-procurement initiatives. The Uniform Electronic Transaction Act (UETA) addresses this issue by allowing electronic signatures in lieu of signatures; however, the level of authentication depends on the type of security used to collect the "electronic signature" (Pacini *et al*. 2002; Belgum 1999; Moreau 1999; Thelen Reid & Priest LLP 1999).

Privacy is also a major concern in e-construction. Contractors and owners bidding on e-construction marketplaces disclose information about themselves and their bids. E-commerce marketplaces and portals may derive value from collecting this information (Millard 2000; Crichard 2003). Additionally, an owner may be in violation of privacy laws if hackers gain access to confidential bidding information of contractors through their servers.

There is another group of legal risks that are not based on conflicts of law and can be addressed at the contract formation stage for each project. Data ownership after project completion, insurance risks for damages due to electronic system failures, and who bears the responsibility for loss of data or risk of hackers in construction projects using electronic project management systems are few examples in this category.

Managerial and organizational challenges

Managerial and organizational challenges are much less emphasized in the literature than the technological challenges. This is contradicting to the fact that almost all industry surveys recognized the importance of those issues (Nitithamyong and Skibniewski 2004). Managerial and organizational challenges identified in the past can be summarized as follows:

- Establishing Return on Investment (ROI) is difficult for many companies. This in turn creates difficulty in making business case to justify investments in e-construction (Nitithamyong and Skibniewski 2004; Veeramani *et al*. 2002).
- General strong cultural resistance encountered by all industry sectors. Resistance to change (Veeramani *et al*. 2002).
- Lack of comprehensive software with features addressing all participants. Current software focus on one entity (Contractor, Owner, or Architect) (Nitithamyong and Skibniewski 2004).

Equal in importance, if not more important, than the listed items are the electronic business models used in e-construction. To evaluate why many e-procurement business models, as an example, pose risks to the construction industry, we must first establish the difference between the types of procurement approaches. Procurement contracts can be negotiated or non-negotiated (pre-established). Also, procurement decisions can be based on long-term value maximizing strategic objectives, or short-term single transaction value maximizing objectives. E-commerce business models are often more efficient for one procurement type than the other. Non-negotiated, short-term single transactions are the least complex types of e-commerce transactions. Often, the one deciding factors for this types of transactions is price. Efficiencies could be gained in a buy-side e-procurement model (e.g. Ariba, Oracle, SAP), seller-side e-procurement model (e.g. Amazon), or an exchange and auction model (e.g. e-bay). On the other hand, negotiated, relation-building transactions are the most complex type of transactions. In this type of transactions, delivery terms, warranty, specifications and schedules can be all negotiated in addition to price. The additional complexity warrants additional precautions if the same business model used in less complex transactions is utilized here. Identity and authentication requirements must be stricter and legally binding; pre-qualifications and reputation building protocols also become more important. Even with more precautions and higher system standards, the business model itself could not be suitable to derive enough efficiency to make the model feasible for such transactions. For example, some claim that reverse auctions are not beneficial for long-term market efficiency (Berning 2003). The business model of reverse auctions work against the market dynamics long-established in the construction industry. The probability that one bidder may bid at a loss in the hopes of making more profit on changes increases the chances of project claims.

Information liquidity and knowledge management challenges

To discuss information liquidity and knowledge management and their importance in e-construction, a distinction between data, information and knowledge must be first established. Data are “facts and figures that are meaningful in some way”; information is “data that has been organized for a particular purpose” (Blair 2002). Knowledge, on the other hand, is more difficult to define; however, it could be described as information intertwined with the intellectual ability to put this information to use (Blair 2002). Knowledge can be either tacit or explicit (Woo *et al*. 2004). Tacit knowledge is the knowledge that experts posses; it is highly context based. Tacit knowledge is further divided into two distinct types: knowledge that can be expressed in logical forms but has not been expressed yet and knowledge that is not expressible (Blair 2002).

Information liquidity is analogous to financial liquidity. Information has more value when it is more readily accessible or, in other words, when it is "liquid". Information liquidity is defined as "the ability to acquire, understand and make use of information when it is needed, where it is needed, in an appropriate context of content and meaning" (Teflian 1999). Information liquidity is critical to electronic transactions. The value of companies in an all-connected world is shifting more towards its ability to harness the power of information, and growing its experience and knowledge base (Teflian 1999).

Information liquidity and knowledge management are particularly challenging for e-construction. Because of the uniqueness of each construction project, much of the knowledge in the industry is tacit knowledge (Woo *et al*. 2004). Tacit knowledge is the least liquid type of knowledge and the most difficult to transform into logical statement and information. This poses a great challenge to e-construction since the value of the network depends greatly on the amount of accurate information that flows in the network.

Integrated e-construction infrastructure framework

It has been shown that e-construction infrastructure is interdisciplinary. E-construction infrastructure is the conglomeration of technological, legal, management and organization, and information infrastructures. Figure 3 illustrates what this paper proposes to be an integrated e-construction infrastructure. The coordination of all these disciplines is a key component for the success of e-construction improvement efforts. The lack of coordination between these components may change the dynamics of the industry or create unequal distribution of risks.

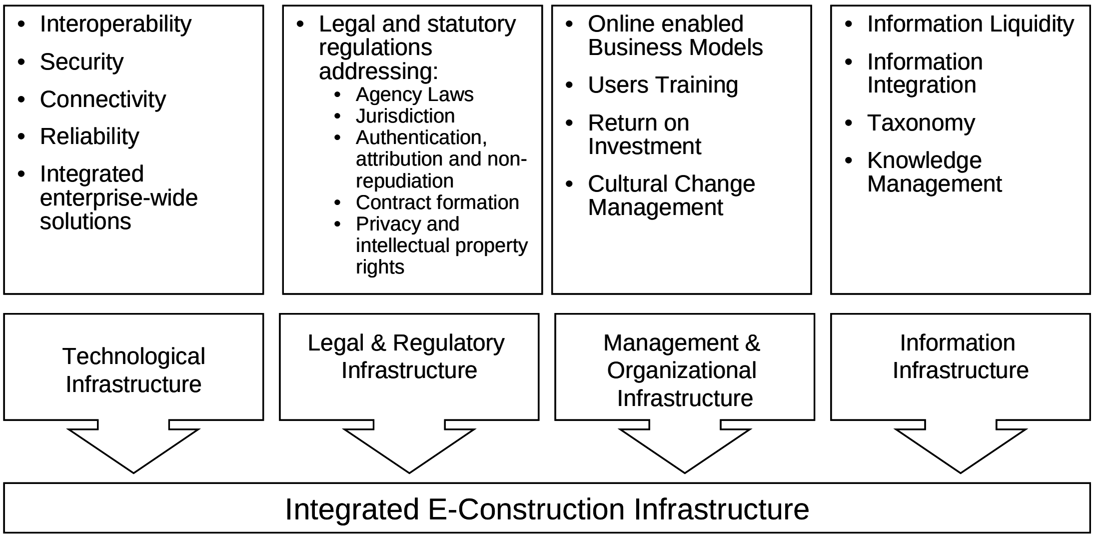

Figure 3: Integrated e-construction infrastructure

One such example that is changing the dynamic of the industry by virtue of changing its risk allocation mechanisms is the conflict between the pre-existing legal doctrine of promissory estoppel and the risk "standard" agreement with software providers. For a contract to be enforceable it must have consideration (Fuller and Eisenberg 2001). For example, a contractor promises not to sell its used equipment that it owns until certain date so that another contractor (potential buyer) arranges its finance, but sell it before that date. The contractor's promise in not enforceable because it lacks consideration. If however, the contractor accepts a down payment, or a certain sum of money in consideration for the promise, the promise is binding and enforceable in court. Promissory estoppel, sometimes referred to as detrimental reliance, is an exception to this rule. Promissory estoppel occurs when "a promise which the promisor should reasonably expect to induce action or forbearance of a definite and substantial character on the part of the promise and which does induce such action nor forbearance is binding if injustice can be avoided only be enforcement of the promise" (Fuller and Eisenberg 2001). Promissory estoppel has been generally utilized in Construction Law to bar bidders from retracting their bids if general contractors depended on their bid price when submitting their bid to the owner. This was justifiable on the basis that contractors had relied on subcontractors' prices, and subcontractors should be responsible for their price since they know when they submit it that contractors will rely on it for their pricing. The general view was that subcontractors have given a promise to provide accurate price in exchange for an opportunity to win the project.

Recently, the expanded use of e-construction required an increased use and dependency on software. Often times the owner or general contractor dictate that they will only receive bids electronically and some times contracts dictate the use of certain project management and collaboration software for all entities working on a given project. This standardization solves some of the interoperability challenges in a given project and improves efficiency in that respect; however, if uncoordinated with the other dimension of the e-construction infrastructure it disrupt the dynamics of the industry.

The case of Mortenson Co., Inc. v. Timberline Software Corp. is a representative example. Mortenson, a general construction contract, purchased licensed estimating software from Timberline. The contractor used the software to estimate its construction costs and prepare bids. It specifically used the software to prepare for a bid that was accepted and then realized that the bid was $1.95 million less than it should have been. It was later discovered that there was a bug in the software that Timberline discovered earlier but though to be un-important. Mortenson sued Timberline to recover $1.95 million in damages. The court held that the shrink-wrap on the software cover included an agreement that limited the liability of the software company to the purchase price of the software. It expressly waived the right to recover consequential damages. The court also held that the licence agreement on the shrink-wrap instructed the purchaser to return the software for a complete refund if they don't agree with the terms. By opening the software pouch, the contractor has accepted a valid way of contracting with a software company and has limited its recovery to the price of the software (Hennigh 2000). However, on the other hand, the court has held the contractor responsible for its submitted price to the owner based on the doctrine of promissory estoppel and on the basis that the owner had relied on the contractor's price.

On a micro-scale, this case illustrates the importance of analysing the risks of using software under a strict licence provisions. Although companies may try to negotiate the terms of the licence agreement with the software company, it is highly unlikely that it will be changed. Bigger contractor may have more leverage negotiating such agreements if they are considering buying a national licensee. Smaller contractors and subcontractors have no leverage in negotiating better terms. On a macro-scale, however, the standardization of software licences agreements to waive the responsibility of the software company of its liability for programming mistakes is in contradiction to the increasing demand from owners to use the same software without agreeing to take part of the added liability to contractors. The same contradiction could be though of if owners require all bidders to use an online marketplace, and the marketplace has established through a click-through agreement that they have the right to collect and use information about participating contractors. Contractors are left with no choice other than not bidding and potentially loosing up project opportunities and/or their business, or give up their privacy rights. This right of only accepting bids using by electronic means or online has even been granted to agencies bidding for public work (Berning 2003).

Another contradiction occurs between the technological aspects of e-construction and the legal aspects. One of the complaints by online project management system users is the large amount of emails they receive everyday. This problem has been exaggerated by the amount of spam mail that is received in the same inbox. Sifting through everyday to determine important email from spam email is a time consuming task that reduces the efficiency of the system. The improvement in technology offered a new solution for this problem in the form of spam filters. The lack of coordination between the use of spam filters and the other dimensions of the e-construction infrastructure; namely the legal aspects, have caused another contradiction. What happens if an important "legal" document is mistakenly filtered as spam? Who is responsible for this mistake if the spam filter is provided as part of the services included with the online project management software? Should we assume that the contractor has the responsibility to search in the filtered emails, provided, they have access to them? If so, then there is no benefit added by using the spam filter. Or should be assume that the owner must check that the contractor received every document that they sent online? If so, then the owner will either have to duplicate everything in paper and send it to the contractor or call to check if online items have been received on the other side, therefore, loosing the benefit of collaboration.

Development of the information infrastructure may also contradict with the development of the technological infrastructure and interoperability requirements. To increase information liquidity some standardization has to happen across the industry. For example, a common taxonomy, and a common product code must be established. On the other hand, interoperability requirements need some standardization in terms of vocabulary and product code structure. Those requirements must be coordinated together or else standardization efforts will fail on both sides.

Many other examples can be cited for the importance of an integrated, coordinated e-construction infrastructure: security requirements must be coordinated with legal requirements; business models and software requirements; and business models and legal regulations.

CONCLUSIONS

E-construction is poised for widespread application in the construction industry. It is being embraced by more AEC firms everyday. The expected exponential increase in the users is matched with an increase in the amount of investment. Users and the industry will ultimately be looking for e-construction to payoff for this investment. This payoff will be derived in terms of added value to the construction operations and more efficiency. To be able to gain this efficiency and value, the infrastructure upon which e-construction is built must be strong and well coordinated. This has not been the case in the past, and is not the case now. The integrated e-construction infrastructure framework is ultimately needed to secure this strong foundation and therefore the future of e-construction. It is also needed to gain the expected benefits and increase the efficiency of contractors and subcontractors.

CONTRIBUTIONS AND FUTURE RESEARCH

Technological challenges have been the sole focus of improvement when it comes to e-construction (Nitithamyong and Skibniewski 2004). This comes as no surprise since it is a topic of highest familiarity for an industry that is accustomed to technical issues and their solutions. The other three groups of challenges have gained little or no attention whosoever. More important, the coordination between the developments of solutions in all four groups does not exist. As the changes are multifaceted and interdisciplinary in nature, the solution must be interdisciplinary. This gap in the literature is acknowledged and identified in this paper, and is collectively addressed in the current research.

A framework for identifying and categorizing e-construction challenges is presented, and an integrated e-construction infrastructure framework is discussed. The conflicts between unbalanced improvements in one aspect of the framework and the others are also discussed. Feature research is needed to identify different methods to coordinate the work of four aspects of the e-construction infrastructure and create linkage between them.

VISUAL REPRESENTATION OF CONSTRUCTION PROGRESS MONITORING METRICS ON TIME-LAPSE PHOTOGRAPHS

Mani Golparvar Fard,[1] Aravind Sridharan,[2] SangHyun Lee[3] and Feniosky Peña-Mora[4]

[1,2,4]*Construction Management Group, Department of Civil and Environmental Engineering, University of Illinois, Urbana-Champaign, 205 N. Mathews Ave., Urbana, IL 61801, USA*
[3] *Department of Civil and Environmental Engineering, University of Alberta, 3-133, Markin/CNRL Natural Resources Engineering Facility Edmonton, Alberta, T6G 2W2, Canada*

A low cost progress data collection technique for construction projects using time-lapse photography or real-time videotaping can provide a wealth of spatial and temporal information for progress data collection. The benefits of using photographs would be maximized if the progress deviations between planned and actual (as-built) performance are visually shown on these photographs. The importance of such visual representation of construction progress is well understood when the participation of diverse parties with different levels of expertise (from owners to subcontractors) is considered. Current formats of monitoring reports (e.g. textual progress reports, progress graphs or charts) may not properly and quickly communicate progress situations and would make understanding of the progress situation difficult. Current methods of monitoring require manual data collection and extensive data extraction from construction documents making progress monitoring a time-consuming process and distracts managers from the important task of decision making. As an effort to address this issue, a visual representation of construction progress is proposed that aims to picture the progress situation on time-lapse photographs (representing actual progress), superimpose the planned progress (obtained from the 4D as-planned model), and provide the clear comparison in an augmented reality environment between as-planned and as-built progress. A series of visualization techniques (e.g. colour and colour gradient) is developed to communicate and visualize detected discrepancies and progress performance metrics. Schedule deviations, construction sequence, budget distribution and earned value analysis metrics (cost performance and schedule performance indices) are also visualized. These techniques if automated could accurately and quickly communicate the progress situation on photographs and provide a powerful tool for prompt progress control decision making.

Keywords: augmented reality, building performance, progress monitoring, visualization.

INTRODUCTION

Owners are demanding faster, better and cheaper project delivery; however, under such conditions accomplishing desired performance during construction would be more difficult. Furthermore, most construction projects or their individual work phases are of relatively short duration and are generally conducted outdoors. Therefore onsite conditions are not permanent and are subject to interruptions and variations such as unforeseen weather conditions (Oglesby *et al*. 1989). These trends and challenges in construction projects require project managers to consider a systematic and comprehensive approach for monitoring and control of the construction progress. Project managers should easily assess and understand the progress status of the project, predict project completion and decide on proper

[1] mgolpar2@uiuc.edu

corrective action before any schedule and cost overruns occur (Song *et al*. 2005). Successful monitoring depends on an assessment of accurate measurement of progress, proper representation of discrepancies between actual and planned performance and timely updates of the schedule. Project management requires most up-to-date design, schedule, cost and performance data delivered in real time and in a comprehensive manner. This is achieved by obtaining an accurate picture of the project progress at any given point in time and implementing efficient control corrective actions.

Current progress monitoring

Current construction monitoring practice is not very efficient and effective, because:

1. *The current progress monitoring is time consuming and labour intensive*: Projects are not constantly monitored and hence it is very difficult to take corrective actions in real time. Current methods require manual data collection, and also extensive data extraction from construction drawings, schedules and budget information produced by project teams in which none is independent (Navon 2006). Field staff collect progress data from the construction site, analyse and deliver them to the project management team in a format specific to their areas of expertise: construction drawings, spreadsheets, bar charts, CPM or progress site photographs or videos. Such discrete and exhaustive reports are produced throughout the life of a project and do not explicitly convey level of performance, problems, their causes, and their impacts on the physical construction situation (Song 2005). Consequently, the project management team needs a lot of time and effort to sort out, prioritize and interpret these data.
2. *Quality of manually collected and extracted progress data is low*: Progress data may be error prone and expensive. Progress information is usually acquired through monitoring of the construction site by a team of field personnel. This may affect the quality of the manually collected data and make it error prone. The ability of anticipating possible outcomes only based on observations depends on the ability of the project management team and their expertise which in turn becomes subjective (Song 2005). The manual process is dependent on the status seen on site and does not reveal the impact of site circumstances on construction activity progressing forward.
3. *Existing methods of measuring progress are non-systematic and in generic terms*: Two of the most common ways to monitor progress are: (a) *Monitoring physical progress in percentile*: this performance metric is used in most construction fields, but it heavily relies on experience and knowledge of the project manager. This metric lacks objectivity and is inefficient at presenting progress due to its abstract nature of physical progress representation (Song 2005); (b) *Budget-based monitoring*: which is based on percentage of the budget paid to contractors with schedule-based inspections. This method of monitoring creates a time lag between progress estimations and schedule updates; besides judgements are usually subjective and misleading especially if a field manager makes an erroneous decision (Shih and Wang 2004). Without a specific comparative analysis on construction plans, sections, resources and cost data, wrong assumptions and inaccurate measurements on the progress status could be made. Mistakes such as overpaying, time delay and overlooking expected delay might occur. Such mistakes may often happen,

nevertheless if the construction process is visualized the progress status would be much clearer and such mistakes could be eliminated and more precise decisions could be made promptly (Song 2005).

4. *Progress monitoring reports are visually complex*. According to Kerzner (2001) and Song *et al*. (2005), 30 to 40 different visual methods are currently being used to represent construction information throughout the life cycle of a project. These graphics and charts contain four sets of information: time, cost, resources and performance to provide an accurate picture of the relations between them. Among various types of information representation, the choice is dependent on the intended audience. For example, upper level management may be interested in costs and integration of activities with very little detail. Summary-type charts normally suffice for this purpose. Daily practitioners, on the other hand, may require as much detail as possible in daily schedules. If the schedule is to be presented to the client, then the presentation should include cost and performance as well (Kerzner 2001). However none of these methods effectively presents multivariable information (i.e. time, cost, resources and performance) in a holistic manner, nor do they reflect the unique circumstances of progress situation (Song *et al*. 2005). It is extremely hard for a project manager to monitor and control all aspects of a project on the basis of first-hand observation alone. Significant information may be disguised during meetings by field professionals. Text-based information is often overly detailed or too technical. Nonetheless, most organizations do not have standardized reporting procedures, which further complicates the situation (Song *et al*. 2005). Under such circumstances, most of the time in schedule revision and coordination meetings is devoted to describing problems and explaining the rationale of decisions and very little time is spent on the real decision making such as the discussion about what-if scenarios (Golparvar Fard *et al*. 2006). The major reason for this is the limitation of proper media that represents these construction discrepancies (Lee and Peña-Mora 2006). It may be difficult to understand the situation clearly and quickly as these representations lack information relating to spatial context and complexities of project components (Koo *et al*. 2000).

In such circumstances, an effective representation of progress discrepancy is needed to save time spent on describing and explaining the situation in the meeting. Visualization of progress monitoring is reported as an effective monitoring process and can assist the project manager in cutting cost and reducing the time for gathering and interpreting data, understanding complex situations and developing better counteractive procedures (Lee and Peña-Mora 2006). Particularly when clients' capability and need to understand complex construction situations are considered, the benefits of visualization techniques would be maximized (Lee and Peña-Mora 2006). As an effort to address this issue visual representation of progress status on time-lapse photographs is proposed. It aims to visualize the actual progress by superimposing the planned progress (obtained from the 4D (3D + time) model) over the photograph (acquired from time-lapse photography or filming) and thus, provide clear comparison between as-planned and as-built progress in an AR (augmented reality) environment. Synchronized time-lapse photography and virtual 4D creates the progress information seamlessly. The methodology proposed to represent performance metrics is based on the earned value analysis method. This method would demonstrate all critical information for the project manager regarding the actual conditions, potential issues, prior concerns and future scenarios.

VISUAL REPRESENTATION OF PROGRESS METRICS

Proposed progress data collection technique

For the proposed application, the inputs are an as-planned 4D model of the project and time-lapse photographs captured by onsite cameras. The as-planned 4D model contains 3D representation of construction components (spatial information on product model) and planning and scheduling information (the process model). The time-lapse photographs contain a sequence of images taken from a fixed point of view that represents the as-built model. The ultimate goal is to automatically overlay and compare the information in the set of images with the as-planned model which allows determining and updating of actual progress status. Figure 1 shows an example of time-lapse photographs taken from a camera on a construction site showing progress.

Figure 1: Examples of progress images from a construction site time-lapse photography camera

Visualization process

Once these progress photographs are collected, the camera should be calibrated, i.e. the relationship between 3D-model coordinates and the corresponding coordinates of the site photograph should be established. Having set the relationship, a camera with the same parameters of the real-world camera is put into the 4D environment. Following that, an image taken from the 4D model would be superimposed on top of the site photograph taken at the same time. This step establishes the correspondence between the site photograph and the planned image. Figure 2 shows an example of a 3D model perspective view where the camera has been registered in the 4D environment superimposed on the progress photograph. The overlaid photograph shows the expected physical progress on top of the site photograph. Superimposition of images provides a clear comparison of what was intended (as-planned) and what has been performed (as-built) (Lee and Peña-Mora 2006).

After this step, a comparison between the as-planned model and as-built model could be easily made. Once the corresponding photograph patch (a small portion of the site photograph of a specific construction component) is found, a series of pattern recognition and image analysing techniques would be applied to extract information from the extracted patch of the photograph. There are robust techniques in computer vision and pattern recognition that could facilitate this process (Forsyth and Ponce 2003). Prior to performing any pattern recognition process, there is a need to establish how these results could be visualized when the superimposition is done. For that, a series of manual comparisons between as-planned models of a series of construction series of manual comparisons between as-planned models of a series of construction projects with their actual progress photographs is done and the parameters of progress monitoring are visualized.

In the following section, the authors will first look into the progress metrics that need to be shown and then will establish visualization techniques representing the project performance.

Figure 2: From top to bottom: site photograph, 3D perspective of the expected progress with the same view as the photograph, and superimposed 3D model on top of the site photograph

Visualization of progress monitoring metrics

Once superimposition of the images is complete and progress status is identified based on comparison of site photographs with the as-planned model, monitored information could be visualized. As mentioned earlier, earned value analysis is used to represent the progress status of the project. Table 1 demonstrates the required monitoring information for project managers during construction.

It is clear that for every step forward in construction progress, the number of 3D model components increases in the 4D environment and as a result visual representation could potentially become more complex (Song *et al*. 2005). Therefore, in order to effectively and consistently use these visualization techniques, a colour spectrum suggested by Song *et al.* (2005) is extended for this work. Table 2 demonstrates that colour spectrum.

Table 1: Critical information sets for project managers during construction phase

	Metric	Description	Visualization form
Basic information	Activity	Description of activities	NA
	Responsibility	List of entities assigned to the activities	NA
	Criticality	Type of criticality	Colour coding
	Float	Amount of float	Colour coding
		Cost distribution of each item based on the percentage of total project cost	Colour coding
Actual performance	% Complete	Percent of work performed	Colour coding
	Productivity	% physical completion / % QAB (quantity-adjusted budget) person-hours used	Colour coding
	CPI	Value of cost performance index	Colour coding/CPI diagram
	SPI	Value of schedule performance index	Colour coding/SPI diagram
Forecasting information	Schedule deviation	Time deviation	Colour coding
	Cost deviation	Cost savings and overruns	Colour coding

Table 2: Critical information sets for project managers during construction phase and the colour spectrum (adapted from Song *et al*. 2005)

Performance	Poor	Perfect	Excellent
Criticality	Critical	Near critical	Non-critical
Float	Float decrease	Float No	Float increase

According to Table 2, blue colour is used to represent those components that need the least management effort while red colour represents components that need more project control action. For instance, in order to represent schedule/cost deviations, red colour could be used on those components that are behind schedule or over budget, green colour for those that are perfect and blue colour for those that are in excellent progress condition. Figure 3 shows the photograph taken from the site and the superimposed image representing status of the progress with different colours.

Cost performance index/schedule performance index

As mentioned before, cost and schedule performance indices (CPI/SPI) of earned value analysis provide robust measurements of current progress status and also serve as key forecasting tools for project management. Song *et al*. (2005) suggested that these two performance indices could be simultaneously represented using a quadrangle colour scheme. Figure 4 shows how the colour spectrum has been modified to represent these two indices simultaneously.

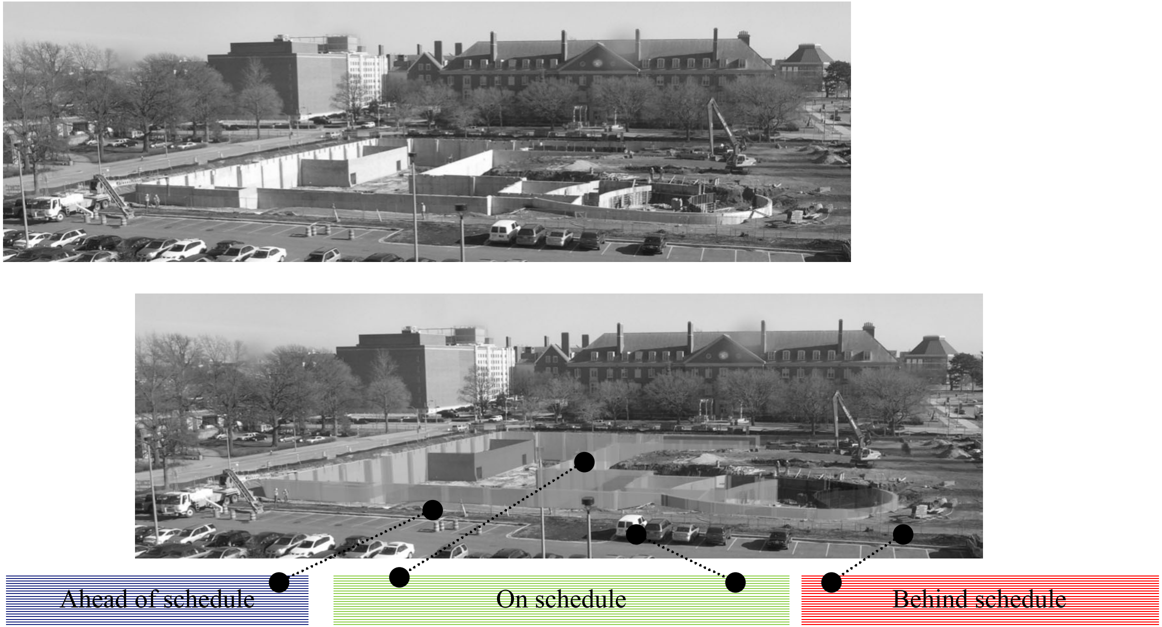

Figure 3: From top to bottom: site photograph, superimposed photograph and colour coding convention (this is a conceptual image and does not reflect the real performance of the construction company)

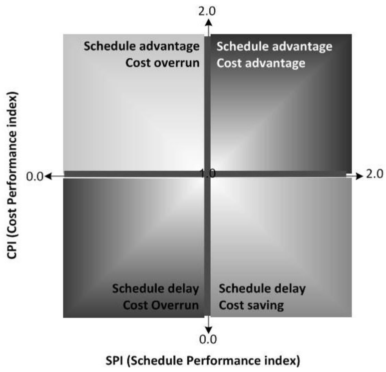

Figure 4: Quadrangle colour scheme of performing indices (extended from Song *et al.* 2005)

Figure 5 demonstrates application of the quadrangle colour scheme on a site photograph. As seen in the figure, foundation walls constructed over a period of five months are represented with different colours. At the current status of the project, there is a delay and cost overrun associated with half of the constructed components. Moreover cost on some other parts is reported to be higher than budgeted cost (represented in yellow colour).

Figure 5: Visual representation of overall project performance (this is a conceptual image and does not reflect the real performance of the construction company)

Concurrent representations of schedule deviations/floats
One of the other visualization methods used to represent deviations/floats is colour gradients. Figure 6 represents the convention suggested by Song *et al*. (2005).

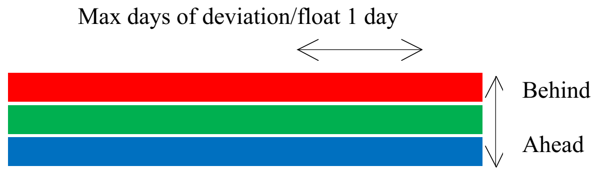

Figure 6: Visual representation of schedule deviation/floats (extended from Song *et al*. 2005)

In this study, the same convention is applied to the site photographs to represent progress deviations. Figure 7 shows an example where concrete pouring has been delayed. As seen, the pouring is happening at the time of taking the photograph. There are parts of the foundation wall that are three weeks behind schedule (i.e. shown in transparent red) and other parts are only a week behind schedule (i.e. represented in solid red).

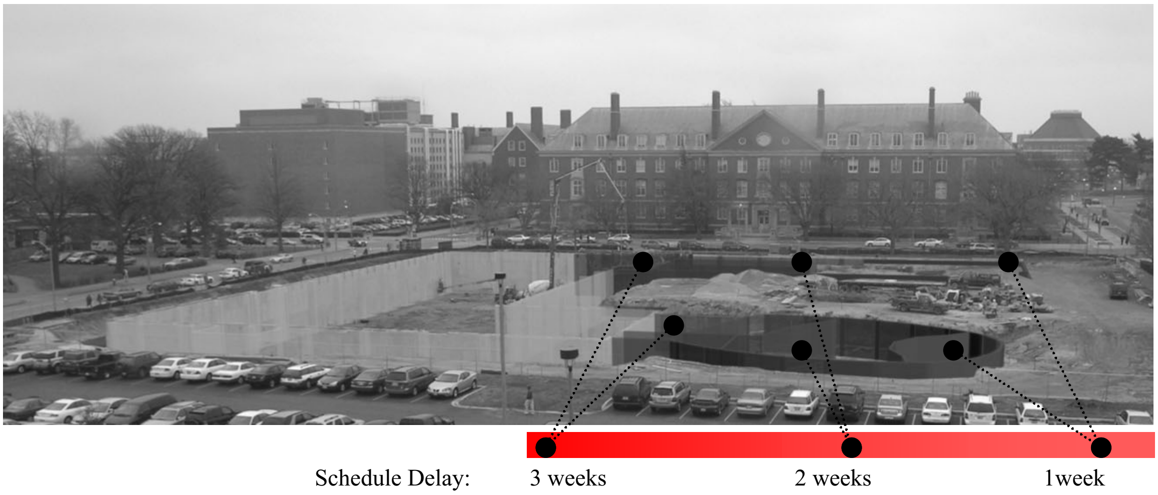

Figure7. Visual representation of schedule deviation/ floats (Disclaimer: This is a conceptual image and does not reflect the real performance of the construction company)

CONCLUSIONS

This paper discussed techniques for visualization of construction progress monitoring, particularly for progress monitoring using time-lapse photography. Compared to other traditional and automated methods used for progress monitoring, the proposed method integrates as-planned with as-built information and visually represents progress status. It could be a consistent and realistic method for representing project performance metrics where spatial and temporal information are represented in a very simple manner allowing project progress prediction and control decision making.

The value of the represented method would be maximized once the whole process is automated, allowing accurate and quick communication of progress situation. This requires further research on configuration of time-lapse photography cameras on site, wherein location and orientation of cameras that satisfactorily detect the progress should be determined. Issues such as occlusion and illumination changes within photographs should also be considered. Once the camera is all set, the progress detection method based on image analysis techniques needs to be robustly designed to

Structure (WBS) represented in the 4D environment should also be developed to incorporate information on temporary structures (e.g. formwork, scaffoldings) for progress analysis purposes.

The visualization techniques also need to be further tested and validated to make sure it represents progress status under different site and weather conditions. Currently authors are conducting case studies, the results of which would be reported in near future.

AKNOWLEDGEMENTS

The authors would like to acknowledge the help and support for this paper by Kip Mecum, Director of Emergency Planning with the Division of Public Safety and all the people at Facilities and Services and College of Business of the University of Illinois at Urbana-Champaign. Sharing of valuable information for the College of Business Instructional Facility project by Gilbane Construction Company and financial support of National Science Foundation is greatly appreciated.

The construction industry is faced with emergent problems and crises every day. Speed and efficiency of problem solving plays a key role not only for the survival but also for improving the service quality of a construction firm. This paper presents a case study on the integration of a knowledge management system (KMS) with an emergent problem-solving system (SOS), namely Knowledge Management integrated Problem Solver (KMiPS), in a local A/E consulting firm. It is found that such integration may result in major benefits that contribute to the improvement of the firm's long-term competitiveness. The case study found remarkable benefits in time, man-hours and cost improvement. Moreover, the knowledge sharing on emergent problem solving among the participating engineers/managers enriches the virtual repository of intangible intellectual assets for the firm.

Keywords: case study, information technology, knowledge management, problem solving.

INTRODUCTION

Construction management activities are fundamentally problem-solving activities (Li and Love 1998), where construction managers and engineers are faced with emergent problems and crises in their daily business operations, e.g. the bidding decision, design modifications, material selections, construction method determinations, site condition variations, change orders, dispute resolutions, etc. Some of the problems are due to the internal nature of the industry, such as the contracting system and fragmented organization; others are caused by the external factors, such as the uncertainty in construction works or environment (e.g. site or weather conditions). No matter which reason causes the emergent problems, the requirements for problem solving are always correctness, speed and efficiency; that is, the problems should be solved correctly, in the shortest time and cost-effectively.

Li and Love (1998) found that construction problems pose several characteristics that should be tackled in order to solve them quickly, correctly and cost-effectively, such as ill-structure nature, inadequate vocabulary, little generalization and conceptualization, temporary multi-organization (TMO), uniqueness of problems, and difficulty in reaching the optimal solution. Two areas of problem-solving research tackle the above-mentioned issues: cognitive science and the decision support system

[1] wenderyu@chu.edu.tw

(DSS). Even though Li and Love had pointed out the importance of research on construction problem solving, no quantitative measures were provided on how well the two approaches have performed in real world implementation.

In this paper, a case study is conducted on a leading A/E consulting firm (China Engineering Consultants Inc., CECI) in Taiwan focusing on the knowledge management system (KMS) for solving emergent construction problems, which forms a Knowledge Management integrated Problem Solver (KmIPS). The KMiPS approach is different from the two approaches described by Li and Love (1998), being based rather on the theory of organizational knowledge creation proposed by Nonaka (1994). Both quantitative and qualitative benefit evaluations are performed. The primary objective of this paper is to present the lessons learned in the case study A/E firm and hopefully such lessons may benefit other construction organizations that are suffering with problem solving every day.

LITERATURE REVIEW

Review of problem solving in construction

Three perspectives of construction problem solving are reviewed in this section, including two perspectives mentioned by Li and Love (1998) and the organizational knowledge creation perspective proposed by Nonaka (1994).

Cognitive processing perspective

The cognitive perspective of problem solving focuses on developing models to explain the cognitive phenomena that occur in the problem solver's mind during the problem-solving process. Simon proposed an 'intelligence-design-choice' (IDC) model (Simon 1965); Newell and Simon modified the IDC model to the 'generate-and-test' (GAT) model (Newell and Simon 1972). In that, the potential solutions to the problem are generated and tested by the problem solver to evaluate their fitness to the solution goals. Other cognitive models can be found in Lang *et al*. (1978) and Cowan (1986). The primary objective of cognitive science is to try to equip the problem solver with explanations and planning capabilities for optimal solutions (Berger *et al*. 1986). However, the findings in cognitive modelling are not strong enough for practical implementation in construction problem solving (Li and Love 1998).

Information processing perspective

In the past decades, researchers have engaged in developing problem-solving systems that can systematically solve well-structured problems step by step. Such systems are named decision support systems (DSSs). Two basic approaches to develop a DSS are operation research (OR) and artificial intelligence (AI). Examples of OR approach include the linear programming (LP) (Srour *et al*. 2006), integer programming (IP), dynamic programming (DP) (Moselhi and Hassanein 2003), system simulation, etc. The AI approach requires a representation scheme to describe the construction problems for the domain experts. Popular AI techniques adopted for developing a DSS include expert systems (ES), case-based reasoning (CBR), artificial neural network (ANN), fuzzy logic (FL), genetic algorithm (GA), etc.

In contrast to cognitive processing, the information processing perspective tackles the problem-solving task in three phases (Li and Love 1998): (1) the formulation of an explicit statement of goals for the problem to be solved; (2) identification of solution space; and (3) selection of the optimal alternative among all feasible solutions. However, either the problem formulation in OR approach or the problem representation in AI approach is difficult for the problem solver owing to the nature of construction problems.

Organizational knowledge creation perspective
Nonaka (1994) proposed a four-dimensional model for organizational knowledge creation (also known as ‘spiral of organizational knowledge creation’) that can be considered as another approach for problem solving. The concept of Nonaka’s spiral of organizational knowledge creation is depicted in Figure 1, where the vertical axis divides the knowledge types into ‘explicit’ and ‘implicit’. The horizontal axis differentiates the ontology of knowledge-creating entities, e.g. individual, group, organization and inter-organization. The problem is solved via the process of knowledge creation. In other words, the problem is communicated between the questioner and the problem solver through ‘socialization’; then, the problem solver documents the problem in words or drawings through ‘externalization’; with some aids of external databases/knowledge bases, the problem solver figures out the solution through ‘combination’; finally, the experience of problem solving is accumulated in the problem solver’s mind for future use through ‘internalization’. The four types of knowledge transformation can be viewed as the phases of the problem-solving process.

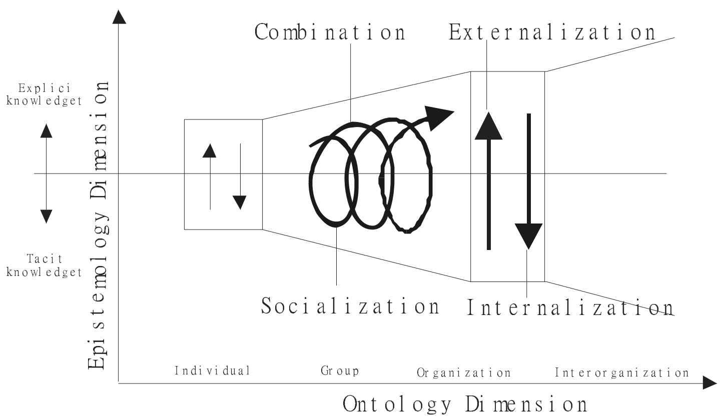

Figure 1: Spiral of organizational knowledge creation (Nonaka 1994)

The theory of organizational knowledge creation forms the theoretical foundation of a modern knowledge management system (KMS). From Nonaka’s viewpoint, problem solving is a process of knowledge creation through socialization, externalization, combination and internalization. Modern KMSs are built on the communities of practice (COPs), which provide forums for members of the organization (or temporary multi-organization) to participate in problem-solving processes in a virtual or real world community. Such a phenomenon is also called the ‘Medici effect’ (Johansson 2002).

Johansson (2002) carried out exhaustive observations of great inventions of the world and proposed a new concept of ‘the Medici effect’ for knowledge creation. According to Johansson, the innovators are changing the world by stepping into the ‘intersection’: a place where ideas from different fields and cultures meet and collide, ultimately igniting an explosion of extraordinary new discoveries. Johansson explains that three driving forces (the movement of people, the convergence of scientific disciplines, and the leap in computational power) are increasing the number and types of intersections we can access. The Medici effect provides a theory for how the communities of practice (COPs) work in a KMS. This approach is adopted by the case study A/E firm in solving its problems.

Review of knowledge management in construction

Knowledge management in construction

Kim *et al*. (2003) proposed a practical method for capturing and representing knowledge that is critical in knowledge management. The method employs a knowledge map as a tool to represent knowledge of a firm. The procedure consists of six steps: (1) defining organizational knowledge; (2) analysing a process map; (3) extracting knowledge; (4) profiling knowledge; (5) linking knowledge; and (6) validating map knowledge. Effective knowledge maps help identify intellectual capital, socialize new members, enhance organizational learning, and anticipate impending threats and/or opportunities (Mezher *et al*. 2005).

Performance measurement of the KMS

There are very few research reports found in the literature on performance evaluation of a KMS. The most relevant work discovered in the literature was a work done by del-Rey-Chamorro *et al*. in Cambridge University (del-Rey-Chamorro *et al*. 2003). They developed an eight-step framework to create performance indicators for knowledge management solutions. Del-Rey-Chamorro *et al*.'s work can be very useful for creating performance indicators of a KMS; however, their work was primarily developed based on the observations of KMS in manufacturing industry. Swaak *et al*. (2000) conducted a survey and concluded that there are two major measurement approaches related to knowledge management results: (1) the questionnaire approach; (2) the multiple indicators approach. A recent work reported by Mezher *et al*. on a KMS in a mechanical and industrial engineering consulting firm (Mezher *et al*. 2005) in the Middle East is closely related to this paper. Their paper details the step-by-step implementation of a KMS in the case study company and lessons learned on the benefits of KMS implementation. Unfortunately, their work didn't describe the evaluation of the performance of the KMS.

BACKGROUND OF CASE STUDY

The case study firm and KMS

The case study A/E firm is one of the top three A/E firms in Taiwan. It was established in 1969 primarily for the purpose of promoting Taiwan's technology and assisting in the economic development of Taiwan and other developing countries. The number of full-time members of staff of the firm is about 1700. The annual revenue of case study A/E firm is around TW$4 billion (US$128 million). According to the information disclosed by the firm, more than 1700 A/E projects were finished in the past 30 years. The total volume (construction budget) of the finished projects exceeds US$300 billion.

The implementation of a KMS in the case study A/E firm started five years ago. Unlike most of other examples of KMS implementation, the A/E firm chose to develop the KMS completely by their own staff members without help of external consultants. Commercial software, Microsoft SharePoint® was adopted to develop the KMS. The system development took one year to complete the prototype. The prototype KMS began to operate after one year of the project commencement. More than 40 communities of practice (COP) were established.

The emergent problem-solving system (SOS)
The SOS system is a special design of the KMS of the case study A/E firm, which provides a tentative forum for emergent problems encountered by engineers/managers. Once the problem is posed as a SOS problem, it is posted in the SOS board on the first page of the KMS for emergent discussions. Such arrangement forces every participant of the KMS to take a look at the posed problem. In this way it generally receives attention and usually has a better chance to be solved by respondents. A problem posed on the SOS board that receives no response within one working day will be automatically removed and transferred to the relevant COP. After then, it becomes regular topic for discussion in the COP.

Type of emergent problems
There are basically 11 categories of emergent problems facing the case study A/E firm: (1) requests of client – requests of the client can be very diversified but emergent; (2) reaction to accident; (3) dispute/contract execution – interpretation of contract articles; (4) material and equipment – onsite activities problems; (5) safety/environment – problems with regulations of the government; (6) requests for engineering information – including the information of bid items or a design, construction method; (7) completion and transfer; (8) SPEC and criteria – technical specifications or design codes; (9) problems with contractors/subcontractors – such as schedule extension or claims of additional cost reimbursement; (10) internal process of the firm – the business/administration process of the firm; (11) others – all problems not belonging to the above categories.

In this case study, the more than 800 problem-solving cases of CECI were collected from June 2004 to September 2006. After reviewing and screening, 586 emergent cases were selected for the case study. The distribution of the 586 emergent problems in the 11 categories is shown in Table 1.

Table 1: Distribution of the 586 emergent problems in the case study A/E firm

No.	Type of emergent problem	Count	%
1	Requests of client	35	6.0%
2	Reaction to accident	6	1.0%
3	Dispute/contract execution	22	3.8%
4	Material and equipment	83	14.1%
5	Safety/environment	24	4.1%
6	Request of engineering information	209	35.7%
7	Completion and transfer	3	0.5%
8	SPEC and criterion	152	25.9%
9	Problems with contractors/sub-contractors	8	1.4%
10	Internal process of the firm	7	1.2%
		586	100%

KNOWLEDGE MANAGEMENT INTEGRATED PROBLEM SOLVER (KMIPS)

In this section, the emergent problem-solving method adopted by the case study A/E firm is an emergent problem solver integrated with the knowledge management system (KMS) of the firm – tentatively named Knowledge Management integrated Problem Solver (KMiPS) – is described in detail.

System framework

The system framework of KMiPS is depicted in Figure 2. The KMiPS is comprised of four major elements: (1) problem diagnosis module – a pre-screening module that assesses the level of emergency of the posed problems; (2) SOS – a specialized community of practice (COP) with the top priority on the firm's enterprise information portal (EIP), which provides a forum for all staff and domain experts to participate in the problem-solving process; (3) domain experts – a pool of the firm's internal and external specialists in all areas related to the services provided by CECI; (4) the firm's KMS.

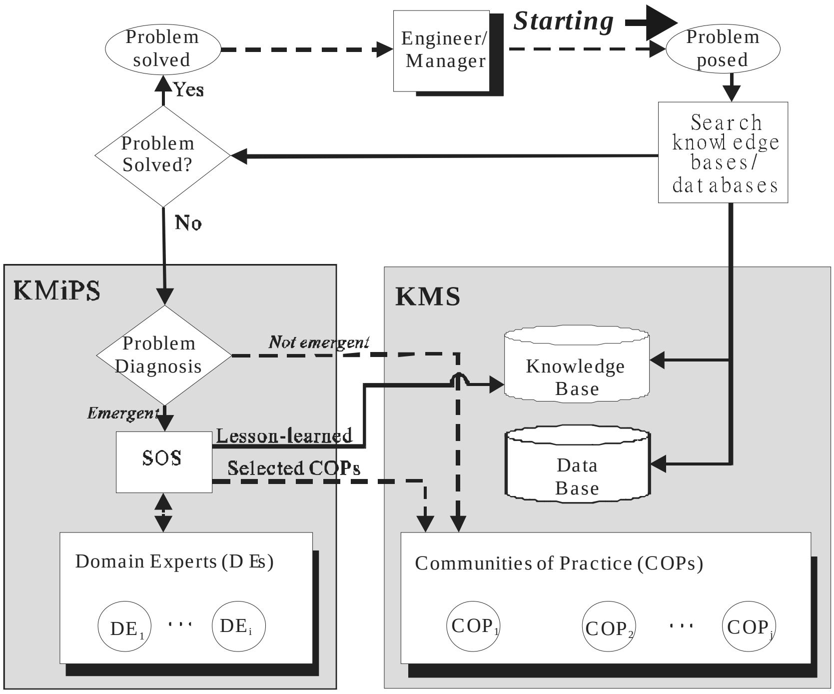

Figure 2: Framework of KMiPS

System operation procedure

The operation of KMiPS shown in Figure 2 follows the procedure: (1) as the problem is posed by any engineer/manager, he/she should search the knowledge bases and databases of the firm first and enter the KMiPS if the problem is not solved; (2) the problem diagnosis module assesses the emergency level to determine if the problem should be posted in the SOS system; (3) if the emergency level of the posed problem is low, it is posted in the related COPs of KMS; (4) if the problem is emergent, it is posted in SOS on the first page of EIP and the selected COPs of KMS simultaneously; (5) domain experts (DEs) from within and outside the firm participate in discussions of the problem solution through a organizational knowledge creation process; (6) as the solution is obtained, the lesson learned from the problem solving is documented into the knowledge base of the KMS for future problem solving.

BENEFIT ANALYSES

The KMiPS described in the previous section has been proven very successful not only in solving emergent problems encountered by the engineers/managers of the firm, but also in accumulating the lessons learned from executed problem-solving cases. In this section, both quantitative and qualitative benefits of the KMiPS system in problem solving are analysed.

Data collection and questionnaire survey

The SOS system was implemented from 1 June 2004. The period of data collection is from 1 June 2004 to 26 September 2006. In total, 654 SOS problem-solving cases were collected. A web-based system was developed for questionnaire survey and data collection. For every SOS case, both the questioner and respondents were surveyed with the KMS. The 'questioner' was asked to provide the following information: (1) whether the problem was solved or not; (2) evaluation of the 'level of contribution' (scale 1–5) to each solution from the respondents; (3) additional time spent on developing the final solution; (4) the numbers of meetings, phone calls and interviews required to develop a similar solution via the traditional approach; (5) average time required for meetings, phone calls and interviews required respectively to develop a similar solution via the traditional approach. The 'respondent' was asked to provide the following information: (1) the time required to develop the solution; (2) the time spent in the office and after work, respectively, to develop the solution. In all, 5011 questionnaire surveys were conducted via the KMS. Finally, 454 complete SOS cases and 3250 valid responses were obtained.

Quantitative benefit analysis

In order to measure the benefits resulting from the KMiPS system, a quantitative benefit model was proposed by Yu *et al*. (2006) to quantify (1) time benefit – saving of time required to solve a problem with KMiPS compared with the time required in the traditional process; (2) man-hour benefit – saving of man-hours required to solve a problem with KMiPS compared with the man-hours required in the traditional process; (3) cost benefit – saving of cost spent to solve a problem with KMiPS compared with the cost spent in the traditional process. Owing to the limitation of the paper, the quantitative models are not reiterated here. Any interested reader is referred to Yu *et al*. (2006) for details.

The quantitative benefits resulting from KMiPS based on the models described previously are: 50.88% of time benefit, 63.53% man-hour benefit and 84.40% cost benefit based on the quantitative models of Yu *et al*. (2006). Other quantitative data describing the benefits of KMiPS are shown in Table 2. From Table 2, it can be seen that the KMiPS saves 8279 man-hours in solving the 454 emergent problems compared with the traditional approach, and this means a cost saving of US$431 354.

Table 2: Data of benefits resulted from KMiPS

Decreased meetings (times)	250
Decreased meeting time (hours)	192
Decreased phone calls (times)	1273
Decreased phone call time (hours)	219
Decreased interviews (times)	324
Decreased man-hours (hours)	8279
Total saving (US$)	431 354

Qualitative benefit analysis

In contrast to the quantitative benefits, identification of the qualitative benefits resulting from KMiPS is difficult. In this research the qualitative benefits were identified through interviews with the engineers/managers of CECI who participated in KMiPS problem-solving. The identified quantitative benefits include (but are not limited to): (1) increase of the firm's intellectual property – during the process of organizational knowledge creation, all participants (including those who read but didn't participate in discussions) accumulate their knowledge related to the posed problem, and the accumulated knowledge may be used another day; (2) solving of problems that could not be solved before – in the traditional approach, the problem is discussed and solved by a taskforce with only limited members from different disciplines, which may exclude the real experts on the problem (who have solved a similar problem before) due to their unavailability for any reason; (3) increase of the Medici effect – when integrated with a KMS, the KMiPS can incorporate all staff of the firm and thus maximize the Medici effect and increase the possibility of problem solving; (4) improvement of client satisfaction – as the KMiPS shortens the required problem-solving time, client satisfaction is significantly greater; (5) improvement of the sense of belonging – the 'sense of belonging' to an organization is a spiritual property that promotes the competitiveness of the firm; with KMiPS engineers/managers and other staff share the pressure of work and the pleasure of problem solving, which improves the 'sense of belonging' of all participants to the organization.

DISCUSSION

Limitations of analysis methodology

The analysis of benefits generated by the proposed KMiPS is based on a quantitative model proposed by Yu *et al*. (2006). In that model, the benefits of a KMS are measured by questionnaire surveys with participants to compare the required efforts for problem solving with both traditional and the proposed approaches. An essential assumption for this model is that the participants are able to 'compare' required parameters of the two approaches. Such assumptions are made in this research, too.

Moreover, the results reported in this paper are based on a case study of a local A/E consulting firm. Different results may be obtained depending on the types of firms, the culture of the organizations and the KM platform adopted.

Merits of KMiPS

Integration of cognitive and information processing perspectives

The KMiPS adopts both the cognitive and information processing problem-solving perspectives. It utilizes the KMS (an advanced information technology) for information processing (searching of knowledge base and database, and problem communication). Moreover, problems with the traditional cognitive science approach are improved with formulated lessons learned of solved cases, so that they can be searched and reused by users.

Improvement of generalization and conceptualization

Generalization and conceptualization (of the proposed and implemented solutions to the posed problems) are enhanced in the KMiPS by matching the domain experts in the solution for a specific problem. The problem of no optimizing or improvement mechanism in the traditional cognitive approach is also improved by a recursive process of solution discussion, where the questioner 'socializes' (the term employed by Nonaka) with respondents via a series of discussions in SOS. The respondent can improve his/her solution based on the solution of previous respondents; and the questioners select the best solution before he/she develops the final solution.

Accumulating lessons learned
The problem of 'temporary-multi-organization' (TMO) in the construction industry is also better tackled by the KMiPS, since the previous problem-solving cases are accumulated with the KMS and modified by the questioners and respondents participating in KMiPS problem solving. Such accumulation of lessons learned not only provides a source of the organization's intelligence, but also develops the learning capability of an organization. It expands the learning scope of the traditional individual cognitive problem-solving approach.

CONCLUSIONS AND RECOMMENDATIONS

In this paper, a case study is conducted on a leading A/E consulting firm in Taiwan. From the case study, a new approach for emergent problem solving, named Knowledge Management integrated Problem Solver (KMiPS) is proposed, which integrates the emergent problem system (namely, SOS system) with the knowledge management system (based on Microsoft SharePoint® platform) to form a new approach for problem solving. The KMiPS approach combines both cognitive and information processing perspectives of traditional problem-solving approaches. It tackles problems encountered in the traditional approaches and provides desirable functions (e.g., improvement of generalization and conceptualization, and accumulating lessons learned). Both quantitative and qualitative benefits are assessed with the KMiPS system. The quantitative benefit analysis shows remarkable time, man-hour and cost improvements based on 454 historical cases. Other quantitative data show 8279 man-hours or US$431 354 of savings. It is thus concluded that the KMiPS approach is very beneficial for the case study A/E firm. It can also benefit other organizations in the construction industry in solve emergent problems.

It is recommended to apply the KMiPS to other types of organizations in the construction industry, such as contractors or EPC firms. The efficiency of problem solving in different types of construction problems needs further research, too. An advanced mode of problem solving to improve the efficiency of problem solving is also worthy of research.

ACKNOWLEDGEMENT

The founding of this research project was partially supported by the National Science Council, Taiwan, under project No. NSC 95-2221-E-216-049. Sincere appreciations are given to the sponsor by the authors. The valuable case study information presented in this paper was provided by CECI, Taipei. The authors would like to express sincere appreciations to the China Engineering Consultants, Inc., Taipei, Taiwan.

KNOWLEDGE-BASED DECISION SUPPORT TOOL FOR DURATION AND COST OVERRUN ANALYSIS OF HIGHWAY CONSTRUCTION PROJECTS

C. Arun[1]

[1]*Civil Engineering Group, Birla Institute of Technology and Science, Pilani, Rajasthan, India*

Highway construction is considered to be one of the important infrastructure developments of any nation, and it involves numerous uncertainties in its planning and execution stages. In addition to uncertainties in the planning stage, which mainly deals with resources, time and technology, uncertainties in the execution stage are mostly site-specific. Owing to this high level of uncertainty, risks associated with site delays are unpredictable and require specific attention by project personnel. The conventional technique for combating time and cost overruns adopts project monitoring using bar charts which are prepared by other conventional scheduling techniques that necessitate crashing of entire train of activities which may or may not be affected by the delay. Hence this paper deals with an innovative decision support tool that can predict duration overrun, cost overrun and activities associated with any specific delay in highway construction projects. This tool utilizes simulation models as a knowledge base for generating the duration and cost overruns. The simulation models for duration and cost overruns of the project are developed based on the nature of the delay, activities associated with the delay and stochastic nature of the duration and cost overruns associated with the activities.

Keywords: cost, decision support tool, delay, probability, simulation.

INTRODUCTION

Development of highways is one of the main contribution factors in addition to sturdy communication lines for infrastructure development since highways act as arteries of national development. In the present system of scheduling construction projects, which utilizes critical path method (CPM) or project evaluation and review technique (PERT), the main input is duration for each activity. The activity duration is mainly dependent on site conditions that are unpredictable during the planning stage of the project. Hence, activities are delayed behind schedule or activity duration is overestimated such that an activity is likely to be completed ahead of the scheduled duration. Hence continuous site monitoring and updating of the schedule is necessary throughout the project to keep time and costs within reasonable limits.

Activity duration for any highway construction project is highly uncertain and this uncertainty is attributed to unprecedented events such as accidents, natural calamities, etc. or due to unexpected conditions such as financial problems, defective designs, corrections because of poor workmanship, etc. The duration overrun, which can occur in any construction project, may be due to one or more risk factors. The influence of each factor may vary with the activity depending on its nature, the accuracy of prediction and any corrective action taken by the project personnel.

[1] arun@bits-pilani.ac.in

Overrun in duration of an activity for any construction project is likely to affect the resources, which in turn affects costs associated with it. Overrun in duration is likely to augment project cost by unproductive manpower and equipment charges, the cost of additional resources for corrective actions, etc. Hence, cost overrun associated with the activity is directly related to duration overrun for the activity. Since duration overrun and cost overrun are interrelated, analysis of cost overrun is inevitable in the project schedule risk analysis.

In the present scenario, project monitoring is carried out by comparing the progress of individual activities and achievements of milestone completions with planned schedules. It is essential for the project management team to predict cost overrun based on various technical and non-technical problems associated with activities. However, cost estimates provide a baseline for assessment of financial performance. Hence, cost overrun is an indication of the influence of overrun risk factors on activities and in turn on the entire project. Project control procedures are mainly intended to identify deviations from project plans rather than suggest possible cost savings. Deviations from plans are likely to cause delay, which in turn result in cost overrun.

Predicting the influence of several parameters on a construction project is a rigorous process. The highway construction project is mostly influenced by more than one external parameter that can cause duration and cost overruns for the project. It is tedious for users to correlate various results from a simulation experiment to predict cost and duration and predict likely duration and cost overruns for the construction project. Hence, a decision support tool has been developed to predict and provide the result in a more realistic sense, which is more relevant to the real-world scenario so that decision makers can predict likely situations in construction sites under prevailing conditions. The decision support tool devised in this research provides duration and cost overruns associated with the probability of occurrence of risk factors provided by user.

DATA COLLECTION AND ANALYSIS

Schedule risk analysis is carried out depending on the nature of the risk and its influence on various activities. Data pertaining to duration and cost overruns of activities were collected from various construction project consultants and project engineers all over India. The data were collected with the aid of a questionnaire, which prompted them to provide duration and cost overruns of each activity in highway construction either in actual monetary value or as a percentage of the total cost. The questionnaire contained standard causes of delays that affect construction activities and activities that are affected by cause of delay. Out of one hundred and twenty questionnaires circulated among various field personnel, 64 responses were obtained. Based on the opinion of senior project implementation consultants in the highway construction sector of India, the main risk factors are categorized as:

- delay in land acquisition;
- obtaining statutory clearances;
- lack of infrastructure and outdated technology;
- delay in procuring materials and equipment;
- unexpected law and order problems;

- unexpected financial problems;
- failure of equipment or parts; and
- changes and correction in design.

The causes of delays are categorized into controllable and uncontrollable delay depending on the nature of the effect on activities. The controllable delays are those for which cause of delay can be predicted in advance and site personnel can take mitigation measures to reduce the effect on activities. Uncontrollable delays on the other hand cannot be predicted in advance and their effect on activities cannot be controlled. Hence depending on the cause of delay there are two sets of probability distribution function for cost and duration for each construction activity. Various causes of delay in the questionnaire, their nature and the activities affected are given in Table 1. This classification of risk is based on the opinions of various project execution consultants all over India. These data, obtained for the entire length of highway affected, are normalized for unit kilometre length for ease and uniform comparison between the projects. This is based on the assumption that the effect of highway construction activity is linearly uniform in nature. The overrun of activity cost and duration can be scaled up depending on the length of the highway affected by it.

These normalized data are analysed stochastically using BestFit 4.5 software developed by Palisade Inc. The software first analyses the data for the computation of the characteristic parameters of the data. Then the goodness of fit (GOF) test is conducted for 16 known standard distribution functions based on Kolmogrov–Smirinov (KS) and Anderson–Darling (AD) test. These tests determine the suitability of data of cost and duration overruns with the standard distribution function. The parameters of these distribution functions, viz. mean, mode, variance, shape parameter, etc. are then established by moment matching method. These standard probability distribution functions are then ranked based on root mean square error between percentile values of the fitted distribution and actual observations.

Table 1: Delay, nature and the affected activities

S.No	**Cause of delay**	**Nature of delay**	**Activities affected**
1.	Delay in land acquisition	Controllable	Site clearing, sub-grade, capping layer, sub-base course, road base course, base course, wearing course, cross-drainage construction, drainage and miscellaneous works
2.	Delay in obtaining statutory clearances	Controllable	Capping layer, sub-base course, road base course, base course, wearing course
3.	Lack of infrastructure	Uncontrollable	Sub-grade, capping layer, sub-base course, road base course, base course, wearing course, cross-drainage construction
4.	Poor and outdated technology	Uncontrollable	
5.	Delay in the availability of design details	Controllable	Capping layer, sub-base course, road base course, base course, wearing course, cross-drainage construction, drainage and miscellaneous works
6.	Inefficiency in the design checks	Controllable	

7.	Delay in procuring materials	Uncontrollable	
8.	Delay in procuring equipment	Uncontrollable	Sub-grade, capping layer, sub-base course, road base course, base course, wearing course, cross-drainage construction
9.	Rework due to improper quality control	Controllable	
10.	Improper planning for the supply of materials	Controllable	Capping layer, sub-base course, road base course, base course, wearing course, cross-drainage construction
11.	Poor coordination between contractors	Controllable	Sub-grade, capping layer, sub-base course, road base course, base course, wearing course, cross-drainage construction, drainage and miscellaneous works
12.	Unexpected law and order problems in the site	Uncontrollable	
13.	Financial problems	Controllable	Site clearing, sub-grade, capping layer, sub-base course, road base course, base course, wearing course, cross-drainage construction, drainage and miscellaneous works
14.	Delay in interconnected activities	Uncontrollable	Sub-grade, capping layer, sub-base course, road base course, base course, wearing course, cross-drainage construction, drainage and miscellaneous works
15.	Delay in payment and other capital facilities	Controllable	Sub-grade, capping layer, sub-base course, road base course, base course, wearing course, cross-drainage construction
16.	Failure of equipment or parts	Uncontrollable	
17.	Changes in design	Controllable	Sub-grade, capping layer, sub-base course, road base course, base course, wearing course, cross-drainage construction
18.	Defects and correction in design	Controllable	Capping layer, sub-base course, road base course, base course, wearing course, cross-drainage construction

From this analysis it has been observed that duration overrun for controllable delay predominantly follows the gamma distribution function and the Erlang distribution function. However the Erlang distribution function is known to be one of the special cases of the gamma distribution function. Hence this can be idealized that duration overrun due to controllable delay follows the gamma distribution function. Similar analysis carried out in relation to cost overrun associated with the same nature of delay indicated that activities predominantly follow the beta distribution function. Distribution functions followed by various activities for both cost and duration overrun of due to a controllable delay are presented in Table 2.

Stochastic analysis was carried out for both activity costs and duration for uncontrollable delay. This analysis indicates duration overrun of the activities predominantly followed the Weibull and beta distribution functions while cost overrun did not show any converging trend to any of the standard distribution functions. Distribution functions followed by cost and duration overruns for each of the activities due to uncontrollable delays are presented in Table 3. Even though each activity followed a different distribution function for cost the majority of the activities followed the Weibull and beta distribution functions, which is evident from Table 2. Simulation models have been formulated based on probability distribution functions presented in Tables 2 and 3 for which the activities influenced by each cause of delay are obtained from Table 1.

Table 2: Probability distribution function for controllable delay

Activity	Duration	Cost
Clearing	Gamma (0.96, 1.87)	405 + 44600 × Beta (0.765, 1.48)
Sub-grade	7 × Beta (1.4, 3.29)	3120 + 205000 × Beta (0.595, 0.839)
Capping layer	Gamma (0.96, 1.87)	1020 + Exponential (113000)

SIMULATION MODELS

Simulation models are formulated separately for each cause of delay using the probability models for the cost and duration overruns of respective activities using Extend Simulation Software developed by Imagine That Inc. The simulation model formulated for each cause of delay is based on activities that are influenced by delay and the probability distribution function for cost and duration overruns for each of the activities based on the corresponding nature of delay. The project activities are represented by a set of attribute delay blocks connected in series and in parallel based on the relationship between activities. The entire system for project overrun is modelled using Generic library functions and Discrete Event library functions which are integrated in Extend Simulation software. A random number generator block is calibrated based on probability distribution functions of the duration overruns obtained for various activities. The probability associated with activity duration overrun is computed using equation blocks for each activity. Attribute delay block delays the entity leaving the block depending on random duration generated by the random number generator block which is devised to generate a random number according to the probability distribution function for that activity. Total project delay is computed using a set of equation blocks, which computes the total time for the entity to reach the end block through various network paths and takes the maximum time out of it.

The probability of duration overrun for each of the activities is computed with the aid of equation blocks with the corresponding equation of distribution function. This value is then used for computation of activity cost overrun using equation blocks using an inverse distribution function for the activity cost overrun in the next set of equation blocks. The total project cost overrun in each cycle is computed by adding up the activity cost overrun. The output of duration and cost overrun is recorded in text file ‘delay.txt’ as a two-dimensional matrix. The duration overrun, cost overrun and the corresponding confidence level are recorded along one row of the matrix with commas separating each field. This text file is used as dynamic knowledge base for the decision support tool. The simulation models for each cause of delay are different from each other in terms of nature and activities involved. As the simulation models can generate scenarios for unit kilometre of construction; a decision support tool has been developed based on the dynamic knowledge base of the simulation models to compute the risk associated with project schedules for any length of highway construction project.

KNOWLEDGE-BASED DECISION SUPPORT TOOL

A knowledge-based decision support tool (KBDST) is developed to provide project personnel with a handy tool to evaluate risk associated with delays in highway construction projects for which the flowchart is presented in Figure 1. KBDST is developed in Java with the aid of simulation models to generate a dynamic knowledge base for cost and duration overruns for the highway construction project. Java 1.3 has been adopted for the development of the expert system, as it is independent of the operating system and can integrate other commercial software very easily. The user is prompted to select the cause of delay to run a corresponding simulation model by selecting one of the predefined causes of delay from the ComboList provided in the interface, which then selects and runs the appropriate overrun simulation model. The system was tested with a user-defined risk factor of ‘delay in land acquisition’ with a confidence level of 92% for a 6km stretch of highway. The tool is programmed to select the appropriate simulation model, which has controllable nature and affects corresponding activities, viz. site clearing, sub-grade, capping layer, sub-base course, road base course, base course, wearing course, cross-drainage construction, drainage and miscellaneous works When predefined 10 000 simulation runs were over the user was prompted to provide the system with the length of highway affected by delay and the level of uncertainty associated with the delay through JText fields provided in interface.

KBDST checks the appropriate column representing probability in the text file ‘delay.txt’ generated by the simulation model, for the value of confidence level provided by the user. It then reads the corresponding row of the matching probability for the duration and cost overrun from the first and second fields respectively. These values are then interpolated linearly for the entire length of highway affected which is input presented by the user. KBDST outputs duration and cost overruns for the entire stretch of highway affected by it at the known level of uncertainty along with activities affected by the delay in the JText fields, which pops up in result window in the interface.

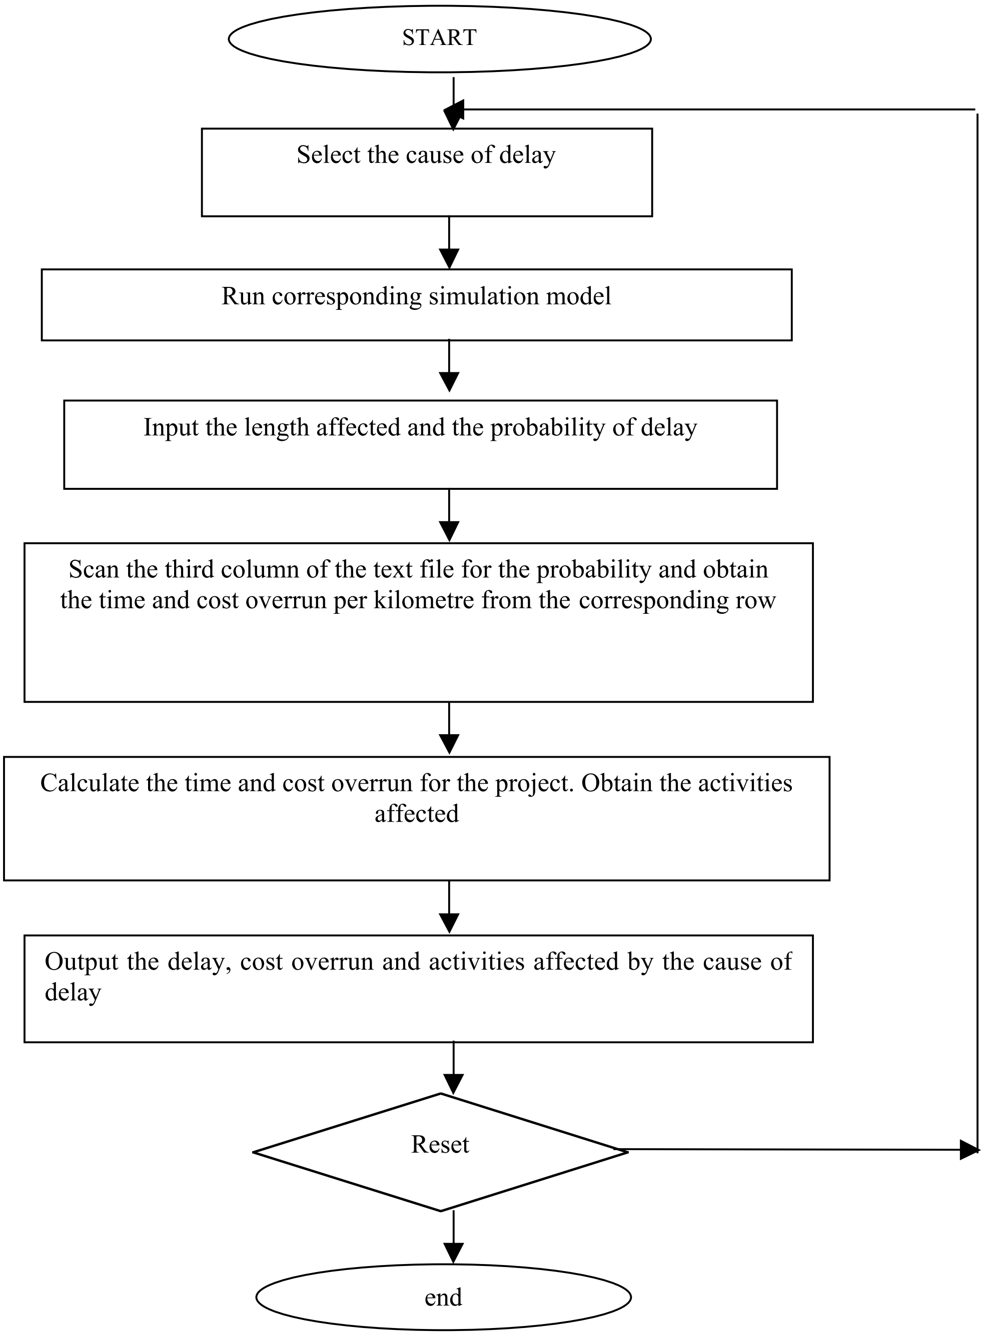

Figure 1: Flowchart of KBDST

DISCUSSION AND CONCLUSIONS

KBDST aids project personnel to evaluate the risks involved in the project in terms of duration as well as cost with known levels of uncertainty. It also provides the user with activities that are affected by any particular risk factor. Hence it provides a hand tool for project managers to monitor and control the activities and predict the activities that are likely to influence the cost. KBDST is designed with the aid of delay analysis simulation model for unit length of highway and the software scales up duration and cost overrun for any length of the highway affected depending on the input provided by the user. The scaling up of the overrun is based on the assumption that cost and overrun for the activities as well as the project are linear in nature. However this assumption may not hold good in all cases of highway construction projects as overrun in duration may decrease with increase in length of project due to corrective actions taken in subsequent stretches. However, the delay analysis is carried out based on actual probability distribution functions followed by activities in highway construction projects rather than assuming a probability distribution function. The validation was carried out using various completed projects and had indicated more than 80% accuracy in predicting the overrun. On condition of anonymity, it was revealed that one 6km stretch of an expressway project in India had incurred a cost overrun and duration overrun of 83.5 lakh Indian Rupees and six months respectively due to ‘delay in land acquisition’. The output of KBDST indicated a duration overrun of 185 days and a cost overrun of 8 334 674 Indian Rupees at 92% confidence level. This study can be extended to other types of construction project and a more realistic risk analysis can be carried out. However, this study can be enhanced by taking into account the interrelation of various risk factors that affect highway construction schedules and by dividing the activities into sub-activities, viz. the cross-drainage works need to be studied separately as this factor is peculiar based on cost and duration aspects.

GENERAL SYSTEMS PERSPECTIVE ON ACHIEVING CONTINUOUS SYNERGY IN A PROJECT ORGANIZATION

Milan Radosavljevic[1]

School of Construction Management and Engineering, University of Reading, Whiteknights, PO Box 219, Reading, RG6 6AW, UK

Studies of construction labour productivity have revealed that limited predictability and multi-agent social complexity make long-range planning of construction projects extremely inaccurate. Fire-fighting, a cultural feature of construction project management, social and structural diversity of involved permanent organizations, and structural temporality all contribute towards relational failures and frequent changes. The main purpose of this paper is therefore to demonstrate that appropriate construction planning may have a profound synergistic effect on structural integration of a project organization. Using the general systems theory perspective, it is further a specific objective to investigate and evaluate organizational effects of changes in planning and potentials for achieving continuous project-organizational synergy. The newly developed methodology recognizes that planning should also represent a continuous, improvement-leading driving force throughout a project. The synergistic effect of the process planning membership duality fostered project-wide integration, eliminated internal boundaries, and created a pool of constantly upgrading knowledge. It maintained a creative environment that resulted in a number of process-related improvements from all parts of the organization. As a result, labour productivity has seen increases of more than 30%, profits have risen from an average of 12% to more than 18%, and project durations have been reduced by several days.

Keywords: construction planning, off-site production, organizational effectiveness, project organization, systems theory.

INTRODUCTION

Project-organizational efficiency

It appears that construction project management has landed in an unenviable position. Projects are becoming more complex, clients more demanding and the market is offering a variety of materials that demand a highly-skilled and professional labour-force. On the other hand, the technology has improved and hence more efficient and positive progress would be expected. There is actually plenty of literature on productivity, methods for measuring productivity, improvements of productivity, factors affecting productivity, etc (Harris *et al*. 2006; Thomas and Završki 1999; Jayawardane *et al*. 1995; Luxhoj *et al*. 1990). Why is it then that, with all the research going on and the new, more efficient equipment to hand, the construction industry has not managed to improve its efficiency considerably? It seems that by mostly concentrating on productivity and on-site management-related issues, construction management research is trying to suppress problems rather than define real causes for

[1] m.radosavljevic@reading.ac.uk

organizational efficiency/inefficiency. Other reasons are complexity and uniqueness of construction projects (Proverbs *et al*. 1998, 1999; Bertelsen 2003). Approach that resulted in higher efficiency in one project may prove totally inappropriate in others.

Projects clearly vary in their efficiency but it remains unclear as to what makes some of them more efficient than others. However, it is clear that project organizations are social systems characterized by their temporal existence at the intersection of various, often very different, permanent organizations (Asheim 2002; Lundin and Söderholm 1995). That being the case, it then must be possible to determine organizational efficiency parameters.

Synergy

One of the most useful organizational efficiency parameter stems from a general systems perspective of social organizations. According to general systems theorists all systems consist of components and relations of interactions between them (Scott 1987; Kajzer 1982; Mesarovic and Takahara 1975; Bertalanffy 1950). They recognize social systems as open systems of relations because they interact with other social systems and their environment. Furthermore, social systems may be constituted by components, themselves being social systems, so they can be viewed as systems of *n*-th order. They are created and recreated through two diametrically opposing processes: *folding* and *composing*. While folding represents a simple sum of components and relations without any changes in the quality of relations and components, composing represents a sum that establishes new relations bringing new quality to a higher order system. The qualitative difference between a composed higher order system and the sum of qualities of “old” sub-systems is thus called synergy. Unfortunately, synergy is often viewed only in relation to frequently unsuccessful corporate mergers making it an unpopular term (Chatterjee 2007). Synergy, however, can also appear within organizations as a consequence of local and global fitness optimization (Dooley 1996). Nevertheless, synergistic effects within organizations are still hugely neglected.

In construction, although not referring to synergy, Dubois and Gadde (2001) address its negative side by viewing construction process as a loosely coupled system. Such a system is disintegrated as soon as one project is complete, and re-established in a different way as soon as a new one has started making coordination and learning repeatedly ineffective. However, synergy within construction project organizations has not yet been addressed appropriately, even though they in many aspects resemble merger situations where synergistic effects have already been extensively analysed (Hitt *et al*. 2001).

Problems, aims and objectives

Cultural clashes, potential issues of mistrust and organizational incompatibility are all difficulties that threat both mergers and construction project organizations. It is therefore of vital importance to be able to appropriately model temporary construction project organizations and their constitutive permanent organizations in order to investigate internal synergistic effects. In light of such understanding, this study aims at uncovering evidence of a continuous synergy in a project organization with the following specific objectives:

- To present systems interpretation of the so called Process Planning Methodology (PPM), a newly adopted short-term planning process in the off-site construction projects that triggers a continuous process of internal re-composition.

- To present relational differences between a traditional approach to managing such projects and the newly established approach.
- To identify potentials for assessing qualitative difference in relations within a continuously recomposed organization.

DATA AND METHODOLOGY

The core of the study is an off-site project in Slovenia that was divided into two separate sub-projects. The PPM was applied to one of the sub-projects by applying a double-loop framework. The other sub-project was managed using firm's traditional project management approach. It is worthwhile mentioning at this point that off-site projects in Slovenia are not characterized by a very distinctive project organization. They are mostly managed through heavy reliance on main contractor's internal organizational structure. This is the main reason why both project and firm organizations are discussed intertwiningly from this point forward.

The details of the PPM, its framework, necessary constitutive elements and application are not relevant here and have been, nonetheless, extensively covered elsewhere (Radosavljevic 2005; Radosavljevic and Horner 2007). Therefore, according to the above objective, this study is to create a theoretical explanation of the organizational restructuring that occurred after the PPM was fully in place.

The mathematics of achieved continuous organizational re-composition, presented according to the systems theory, forms a major part of the methodology and follows the work of Kajzer (1982), and Mesarovic and Takahara (1975). This was found to be the only analytical approach that could be used in order to illustrate these relational changes.

SYSTEMS PERSPECTIVE

Traditional project management

One of the sub-projects was managed traditionally where firm's project managers, although being responsible for a number of projects, were operationally intertwined in the firm's hierarchy. All off-site construction projects thus required full commitment of firm's departmental directors (i.e. purchasing, R&D, quarries, production units, etc.). These are responsible for managing supporting activities like logistics, material testing, supplies, etc. The traditional approach normally resulted in delays due to seemingly unknown reasons and poor relations within project and firm organizations. Project delivery was regularly under pressure due to disputes and power clashes between various directors and project managers. The systems view of the firm organization reveals major reasons for often unsatisfactory project delivery. Figure 1 shows that departments may be subject to four types of boundary relations, namely managerial, interdepartmental, inter-level and external relations. Boundary relations can be further split into internal (between sub-systems) and external boundary relations (between sub-systems and the environment):

$$BR_i^{(n-1)} = IBR_i^{(n-1)} + EBR_i^{(n-1)} \tag{1}$$

where,

$IBR_i^{(n-1)}$ internal boundary relations of constituent sub-systems in a system of *n*-th order

$EBR_i^{(n-1)}$ external boundary relations of constituent sub-systems in a system of *n*-th order

Equations 2 and 3 show that internal boundary relations between sub-systems (level *n-1*) represent relations within an organization so they can be called system relations at the *n*-th level. Clearly, it is of interest to organizations to maximize internal relations in order to improve communication. This can only be improved through an increase of internal system relations (i.e. relations between sub-systems).

$$SR^{(n)} = \bigcup_{i=1}^{m} \bigcup_{j=1}^{m} \left(BR_i^{(n-1)} \cap BR_j^{(n-1)} \right); \quad i \neq j \tag{2}$$

$$SR^{(n)} = IBR_i^{(n-1)} \tag{3}$$

However, this tendency towards better communication goes on account of external relations, making highly hierarchical and departmentalized organizations alienated from their environment (Levinthal 1991; Child 1984). Because boundary relations consist of internal boundary relations (system relations) and external boundary relations, one can maximize system relations only to the detriment of external boundary relations. In other words, maximizing system relations minimizes external relations (see Equations 4, 5 and 6).

$$IBR_i^{(n-1)} = BR_i^{(n-1)} - EBR_i^{(n-1)} \tag{4}$$

$$SR^{(n)} = BR_i^{(n-1)} - EBR_i^{(n-1)} \tag{5}$$

$$SR_{\max}^{(n)} = IBR_i^{(n-1)}; EBR_i^{(n-1)} \to \emptyset \tag{6}$$

where,

$IBR_i^{(n-1)}$ internal boundary relations of the constituent sub-systems

$EBR_i^{(n-1)}$ external boundary relations of the constituent sub-systems

$SR_{max}^{(n)}$ maximized system relations at the *n*th level.

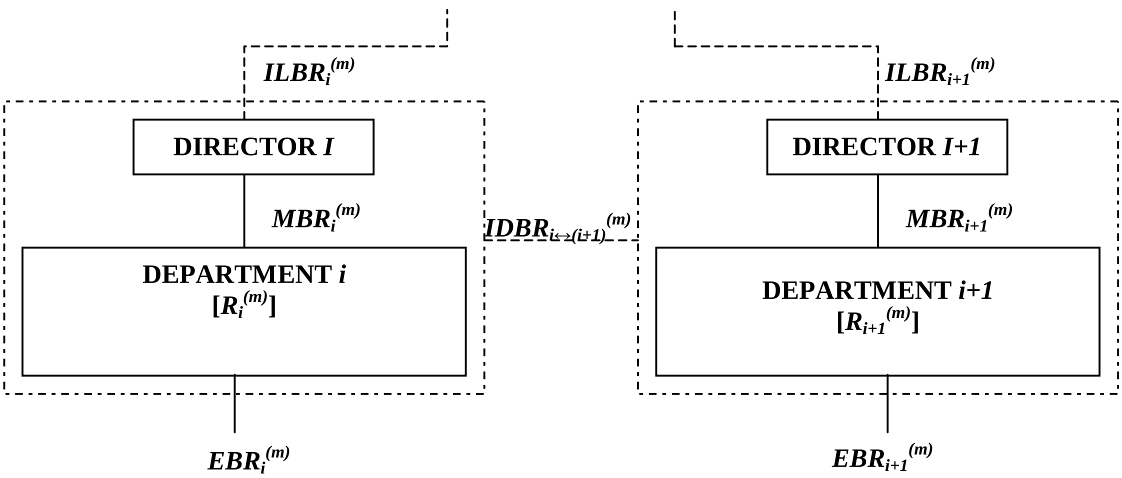

Figure 1: Relations of interactions within departments at m-th level ($R_i^{(m)}$ represents internal relations in i-th department; $MBR_i^{(m)}$ represents managerial boundary relations; $IDBR_{i\leftrightarrow(i+1)}^{(m)}$

represents interdepartmental boundary relations; $ILBR_i^{(m)}$ represents inter-level boundary relations and $EBR_i^{(m)}$ represents external boundary relations

With a rising number of levels and departments, external relations become restricted to only a limited number of people, making organizational adaptability to external changes extremely difficult (Robbins 1998; Pugh 1997). They become prescribed within bureaucratic rules hindering individual participation and initiatives (Torrington and Hall 1998). Furthermore, maximizing system relations necessarily deteriorates creativity of human beings by restricting their possible interactions outside the prescribed ones.

The organization of the traditionally managed sub-project suffered significantly due to these problems. On top of issues within the project organization, the project manager had to deal with obstacles internal to the firm. This was also claimed to be the main reason for frequent fire-fighting and a lack of time.

Process planning methodology
The second sub-project was managed using the so-called process planning methodology by dividing it into several week-long sub-processes. A process is here defined as a sum of successfully accomplished activities, which are interconnected by a specific logic of order to represent a functional totality. The PPM relies on improved definition of planning, a process planning group and two iterative improvement loops but a much more detailed description of the case study can be found elsewhere (Radosavljevic and Horner 2007).

Interestingly, the new planning methodology changed the operational structure of the firm's organization. It has become project-centred with a control group having a major and fluctuating position between emerging *Greater production* and *Greater management* sub-systems (see Figure 2). This is probably one of the reasons that even traditionally managed sub-project was completed within budget and on time.

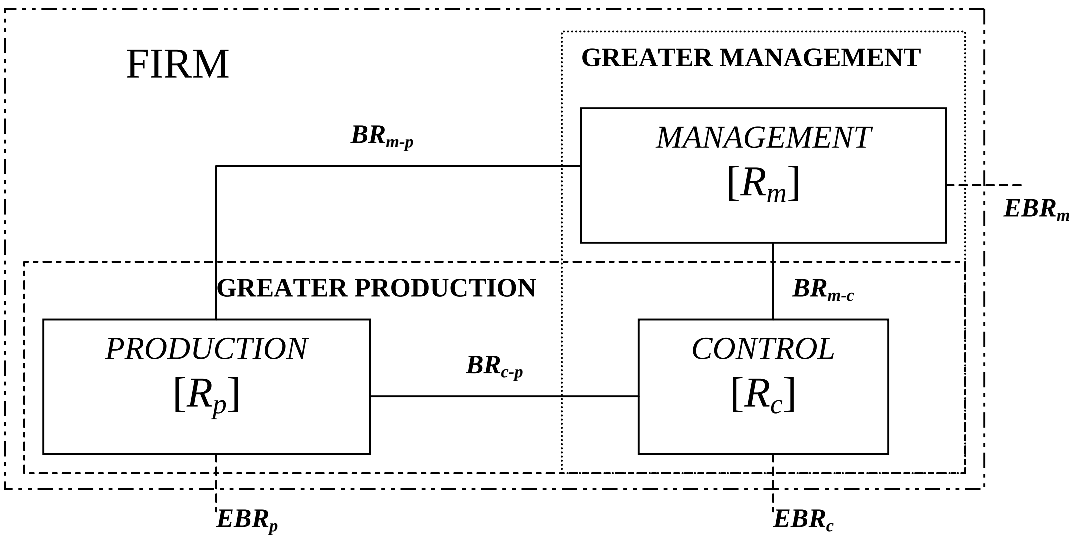

Figure 2: PPM-induced relations of interactions that only divide a firm into three functionally different sub-systems (production, control and management).

In the above declaration, *Management* involves all those managers that, unlike the control group, do not participate in production. In the similar note, *Production* consists of all production workers that do not participate in management. The control group is thus a dynamic link between *Management* and *Production*. Because of its alternating participation in production and management, *Production* with *Control* represents the *Greater production* sub-system and *Management* with *Control* represents the *Greater management* sub-system. The dynamic characteristic of *Control* as a constituent category of both *Greater production* and *Greater management* sub-systems plays a mediatory role between *Production* and *Management*. The question is why boundaries between *Production* and *Control* and between *Management* and *Control* are not so called "real" internal boundaries? What, then, is a major difference between the managerial boundary relations from Figure 1 and these relations? The essential point is that the boundary between departments and the managerial sub-system prevents direct participation of departmental members in the activities of the managerial sub-system which consequently diminishes individual initiative (Torrington and Hall 1998). Members of *Control*, on the other hand, participate in the activities of both *Greater management* and *Greater production* sub-systems (everyday work). The *Control* sub-system participates in the *Greater production* and *Greater management* sub-systems and is not isolated from them. They actively participate in all activities within *Greater management* due to the feedback they receive from *Production* and they also facilitate managers to modify their decisions according to what is happening in the production. Their position within organizational structure is equal to any other (positions are not hierarchically differentiated). They also actively participate in *Greater Production* because their role is to implement agreed activities. Members of *Production*, due to their participation in the production, usually cannot fully participate in process planning and, on the other hand, members of *Management* most of the time cannot be present and operationally do not participate in production. This is the only "pure" internal boundary in this case. It is equivalent to the ones between departments and different levels, but such a boundary is physically and functionally indispensable.

$$R_p^{(1)} \cap R_m^{(1)} = \emptyset \qquad (7)$$

Management and *Production* are two operationally separate sub-systems that do not share common internal system relations (see Equation 7). *Control* is a first order sub-system that is subject to a dynamic membership by being a constitutive element of both second order sub-systems. This is a unique property that enables a continuous process of decomposition and re-composition. Firstly, members of a control sub-system participate in the production by gathering knowledge about the processes of production, accompanying difficulties and possible solutions that might be revealed by observing the processes. When the *Control* members participate in the process planning, they trigger composition of the *Greater management* sub-system and decomposition of the *Greater production* sub-system. During the process of composition, they bring in new relations enriched by gathered knowledge from *Greater production* and help to bring up ideas for enhancing the process of production. They move back on a daily basis and recompose the *Greater production* sub-system by bringing in iteratively derived instructions for the planned processes of production. Such iterative and dynamic processes of re-composition and decomposition are necessary and, regardless of the level, create changes in relations within all sub-systems. The most significant changes appear among the internal boundary relations that are now split into two new categories, pure and seemingly boundary relations, in the following way:

$$\sum_{j=1}^{2} SR_{j*}^{(2)} = \sum_{j=1}^{2} R_{j*}^{(2)} - \left[\sum_{i=1}^{3} R_{i*}^{(1)} \right] = \sum_{i=1}^{3} IBR_{i*}^{''(1)} \tag{8}$$

where

$$\sum_{i=1}^{3} IBR_{i*}^{''(1)} = IBR_{i*}^{'(1)} + IBR_{i*}^{(1)} = BR_{C\leftrightarrow M}^{'(1)} + BR_{C\leftrightarrow P}^{'(1)} + BR_{P\leftrightarrow M}^{(1)} \tag{9}$$

$$IBR_{i*}^{(1)} = BR_{P\leftrightarrow M}^{(1)} \tag{10}$$

where

$IBR_{i*}^{''(1)}$	all boundary relations (real and seemingly) of *i-th* first order sub-system
$SR_{*j}^{(2)}$	system relations within greater management (*j=1*) or greater production (*j=2*) second order sub-system
$R_{*j}^{(2)}$	internal relations within greater management (*j=1*) or greater production (*j=2*) second order sub-system
$R_{i*}^{(1)}$	internal relations of *i-th* first order sub-system
$IBR_{i*}^{'(1)}$	internal seemingly boundary relations of *i-th* first order sub-system
$BR_{C\leftrightarrow M}^{'(1)}$	seemingly boundary relations between control and pure management
$BR_{C\leftrightarrow P}^{'(1)}$	seemingly boundary relations between control and pure production
$BR_{M\leftrightarrow P}^{'(1)}$	boundary relations between pure management and pure production
$IBR_{i*}^{(1)}$	"real" internal boundary relations of *i-th* first order sub-system.

If we now consider the above dynamic participation of *Control* in the relational domain of both the second order sub-systems and take in the account Equation 9, then boundary relations between *Control* and *Management*, and between *Control* and *Production* are clearly not "real" boundary relations. This is so because of iterative internal relational activity within both second order sub-systems, which these seemingly boundary relations depend on and can be expressed in the following way:

$$BR_{*(C\leftrightarrow M)j}^{'(1)} = f\left(R_{*(C\leftrightarrow P)j}^{(2)}\right); \quad j = 1,2,\ldots,\infty \tag{11}$$

$$BR_{*(C\leftrightarrow P)j}^{'(1)} = f\left(R_{*(C\leftrightarrow M)l-1}^{(2)}\right); \quad l = 2,3,\ldots,\infty \tag{12}$$

where

$R_{*(C\leftrightarrow P)j}^{(2)}$	internal relations within greater production in *j-th* participation of the control sub-system
$R_{*(C\leftrightarrow M)l-1}^{(2)}$	internal relations within greater management in *(l-1)-st* participation of the control sub-system.

Moreover, the system relations within *Greater Management* and *Greater Production*, constituted by the internal boundary relations of their integrands, can entirely depend on these seemingly boundary relations. Even if "real" boundary relations between *Production* and *Management* are halted, a firm would still preserve its operational activity and would not disintegrate, which can be shown by:

$$\coprod_{j=1}^{2} SR_{*j}^{(2)} = BR_{*C \leftrightarrow M}^{'(1)} + BR_{*C \leftrightarrow P}^{'(1)}; \quad BR_{*P \leftrightarrow M}^{(1)} \rightarrow \emptyset \tag{13}$$

In other words, pure internal boundary relations are not necessary conditions for the functioning of such an organization. All sub-systems (regardless the level) can therefore maintain an equability of relations with the external environment. The firm can continuously absorb external project level or market level disturbances and subordinate them to the maintenance of their integral organization. Such unrestricted equability takes place with no harm to the system relations (see Equation 13). Furthermore, by implementing the PPM, *Greater Management*, in this manner, deliberately incorporates components of systems operationally outside of a firm, such as a number of clients and designers' representatives.

The synergistic effect of the continuous membership duality fosters project-wide integration, eliminates the need for internal boundaries, and creates a pool of constantly upgrading knowledge. In the above case, it maintained a creative environment that resulted in a number of process-related improvements coming from all parts of the organization.

Continuous synergy in the PPM

Continuous re-composition, experienced in the PPM-managed sub-project, is hence a process that continuously regenerates involved sub-systems, with new characteristics. In the similar way, by regenerating sub-systems, it also changes quality of the constituent components. The composition **C** of *Greater Management* and *Greater Production* second order sub-systems can be expressed in the following way:

$$S_*^{(2)} = \mathbf{C}_{i=1}^{m} S_i^{(1)} \tag{14}$$

so that:

$$S_*^{(2)} = S_*^{(2)}\left(C^{(2)}, R_*^{(2)}, BR_*^{(2)}\right) \tag{15}$$

where

$S_*^{(2)}$ new system of the second order

$C^{(2)}$ set of components of the second order system (they obviously do not change)

$R_*^{(2)}$ changed set of internal relations in the second order system

$BR_*^{(2)}$ changed set of boundary relations in the second order system.

In this manner, for an *n*-th order system $S^{(n)}$ Kajzer (1982) determines composability as a measure of quality $q_i^{(n)}$:

$$S^{(1)} = \left\{\left(S_i^{(1)}, q_i^{(1)}\right); \quad i \in I\right\} \tag{16}$$

The quality of the second order system in Equation 14 is therefore different from the sum of qualities of its first-order sub-systems before the composition. This difference of the sum before and the resulting second order system after the composition is called synergy. However, synergy is only suitable if it brings new, better quality in relations, which can be expressed as follows:

$$q^{(2)} > \sum_{j \in J} q_j^{(1)} \tag{17}$$

This is a necessary condition for composability but not sufficient because one may increase the quality of the original systems without composing them. The process of continuous re-composition yields a set of compounds of the second order system $S_i^{(2)}$ with its related measures of quality $q_{ip}^{(2)}$:

$$S_i^{(2)} = \left\{ \left(S_{ip}^{(2)}, q_{ip}^{(2)} \right); p = 1,2,...q \right\}; \quad i \in I \tag{18}$$

It is hoped that an iterative process will yield optimal possible quality $q_{io}^{(2)}$ after every iteration in the following way:

$$q_{i0}^{(2)} = \max \left\lfloor q_{ip}^{(2)} \right\rfloor; \quad i \in I; \quad p = 1,2,...,q \tag{19}$$

with a qualitative leap $\rho_i^{(2)}$:

$$\rho_i^{(2)} = q_{i0}^{(2)} - q_i^{(2)}; \quad i \in I \tag{20}$$

This qualitative leap is a positive synergy that the PPM hoped to achieve after every *Control* membership iteration. Quantifying synergistic effects in such a way is not yet possible and future research will be needed. However, final results were very promising. The PPM-managed sub-project resulted in an increase of labour productivity by more than 30%, profits rose from an average of 12% to more than 18%, and the project duration has been reduced by three days (Radosavljevic and Horner 2007).

CONCLUSIONS

Although problems of hierarchical departmentalization have been well documented, no studies have been found that would produce a generic underlying theory. The aim of this research was therefore to uncover evidence of a continuous synergy in the PPM-based project organization that, in the case of the firm under study, was intertwined with the firm’s organization.

The mathematical general systems perspective of the traditional and PPM-based sub-systems reveals important and as yet unanalysed relational differences. Changed planning methodology has had a profound effect on how the firm has operated. While departmentalized structure relies on increased internal system relations that diminish its ability to effectively relate with the external environment, PPM through its *Control* sub-system establishes a dynamic link between *Production* and *Management* that enables external adaptability. Although experienced in practice, this huge difference was only truly depicted with the general systems theory.

The importance of this perspective is obvious. It enabled the firm to investigate relational weaknesses in the organization and it also exhibits great potentials for the pre-analysis of organizational compositions regardless of the organizational structure. General systems theory thus provides a vehicle for understanding relational differences between different organizational settings.

The most important message of this particular research is thus not the improvements achieved through the implementation of the new approach *per se*. What really matters is the ability to explain major differences between the traditional and this new approach. General systems theory provides a generic mathematical approach to scrutinize organizations and reveals why some of them are more successful than others.

PSYCHO-SOCIAL APPROACH FOR DISCERNING THE DICHOTOMY OF COMPETITION AND COLLABORATION TO ADVANCE MUTUALISTIC RELATIONSHIPS IN CONSTRUCTION

Abbas Ali Elmualim[1]

Innovative Construction Research Centre, The School of Construction Management and Engineering, The University of Reading, RG6 6AW, UK

Construction is largely viewed as a fragmented industry. Such fragmentation is due to the various cultural values, processes and interests of diverse participating organizations in project delivery. The industry is further viewed as being of low trust with competitive and adversarial relationships as the dominant strand of its culture. A theoretical critique of competitive and collaborative attitudes pertinent within the construction industry is reviewed. This critique reviews the rhetoric of collaboration in the UK construction industry. The critique is further extended to draw distinctions between psycho-structural and the socio-structural dimensions of culture to investigate and evaluate cultural changes and adaptations. This is in addition to understanding power distribution and its influence on competitive or collaborative attitudes. This is vital in order to understand the underpinning rationale behind adversarial and mutualistic models of behaviour through their manifestations within the construction industry's managerial practices. This psycho and socio structural approach advocates the paramount advantages of mutualistic management practices for a diverse/fragmented industry such as construction depicting various schools of thoughts, which include communication theory, system thinking, feminism, and environmental groups.

Keywords: adversarial behaviour, collaboration, competitiveness, culture and mutualism.

INTRODUCTION

The construction industry is widely viewed as a fragmented and diverse industry due to its project based nature. According to Wild (2002), 80% of construction projects involve a one-off clients and are non-recurrent. There is mounting pressure for construction to collaborate. The discourse of change towards collaboration espouses an improvement in contracts, communications and management (Egan 1998). The recommended change remains an aspiration of the policy makers (Wild 2002). The inception, design, construction and operation of any construction project require the participation of various agents according to their professional knowledge, experience and their required input into the specific project. By nature, the diverse number of participants in construction and the delivery of projects require collaboration by these participants. However, each constituency of participants has its own agenda and interests, and mobilizes its resources, knowledge and practices as part of the project to meet its interests. These interests are mainly financial to achieve a competitive edge of their competitors (Elmualim *et al.* 2006). Hence, there is a stringent need for

[1] a.a.elmualim@reading.ac.uk

collaboration between various organizations from architectural practices, consulting engineers, general contactors, specialized sub-contractors, manufacturers and material suppliers as well as management firms in the delivery of construction projects. This intra-organizational collaboration is mirrored by an inter-organizational practice. Furthermore, it is argued that individual and organizational behaviour is highly influenced by national culture (Hofstede 2001, 2003). The conflict arises when each organization or an individual within an organization aspires to meet their own interest ignoring the interest of others. The dichotomy is that many firms and individuals while engaging in collaborative practices seek opportunities to advance their interest through competitive practices. Such practices of collaboration and competition at both levels of intra or inter-organizations have caused the emergence of a culture of adversarial attitudes (Egan 1998), which is pertinent within construction and is decried by all (Green and May 2003). The most compelling and pressing question is why organizations and individuals develop such paradoxical practices of competition and collaboration? This paper attempts to address this paramount question by adopting a psycho-social approach that seeks to understand such dichotomy and advance a paradigm that is most befitting to healthy and genuine collaborative relationships in construction.

UNDERSTANDING CONSTRUCTION

Fragmentation of the UK construction industry

According to the figures from the Department of Trade and Industry (DTI), the UK construction employs more than 1.6 m people with a third registered as self-employed (DTI 2003). The UK construction industry is dominated by small and medium enterprises with annual output of more than £83.5bn. The sector is highly fragmented with low levels of workload continuity, little interdependence and communication and lack of trust. According to Egan (1998), this sector's fragmentation led to the extensive use of subcontracting and prevented the continuity of efficient and effective teamwork. However, this fragmentation assisted organizations in having greater flexibility to deal with highly varied workloads. Eventually the sector's overriding practice is characterized by adversarial relationship, low cost, short-term profits and opportunistic behaviour. Best practice initiatives introduced teamworking, collaborative working and the call for a higher level of trust are failing to bring about dramatic changes that are sought (Green and May 2003).

Despite the domination of small and medium enterprises for construction, the majority of work is carried out by large firms. These large construction firms are typically seen as hollowed-out organizations in that very few of them actually carry out the work themselves. Virtually all their work is carried out by subcontractors or by subcontracted labour. The large firms are thus more involved in managing the processes on projects rather than doing the work themselves. This has implications in that if collaborative relationships are to be formed to promote the interests at all levels closer to the workface and users, then this will probably have to take place with people from different organizations. Secondly, it means that large firms have limited influence on promoting effective communication at the levels that the work actually gets done. However, they have a great deal of influence in promoting learning among 'white collar' workers. A significant factor explaining the negative examples of intra or inter-organization collaboration is the relatively low level of trust that exists between organizations and individuals within these organizations. The importance of trust in facilitating knowledge sharing is increasingly being recognized, with a lack of trust likely to inhibit the extent to which people are willing to collaborate with each other (Hislop 2005).

Having said that, most large construction firms are project based organizations in that the firm together with all its employees are not all situated in one location but are ‘dispersed’ and are thus viewed as a conglomeration of various project based teams. The large contracting firm is therefore essentially an aggregation of the projects with which it is involved with at any point in time. Coupled with this, construction projects run to very tight timescales; thus, coming together to meet, for the purpose of sharing knowledge, is not seen as a priority for a number of project staff. Getting staff to collaborate online also poses its own difficulties in that on a number of projects the IT infrastructure which houses collaboration software, is not always available (Egbu 2004). Such reasoning is seen as the driver for the industrial recipe of construction.

The industrial recipe of construction has been defined as the overriding culture that typifies a particular industry. The industry recipe is thought to be particularly strong in the construction industry, the flavour of which is captured in the perceived view of the traditional design-tender-build method of procurement, in which design is separated from construction and the system is characterized by fragmentation, friction and mistrust. Newer forms of procurement, such as construction management and partnering, are being used, although slowly, as vehicles to change the industrial recipe. The aspect of mistrust that stems from the industrial recipe has particular relevance to the application of collaborative frameworks between and within organizations. Collaborative relationships are deemed to develop at their best in environments where trust is prevalent.

Dichotomy of competition and collaboration in construction

Much of the current discourse of competitiveness is derived from Michael Porter’s typology of competitive advantage (Porter 1980; Porter 1985, 1990). While Porter’s work initially focused on guiding firms whether or not to enter a particular industry, it has since become more commonly used to analyse relative market power as a means of informing strategic action. The analysis is often know as ‘Five Forces’, referring to the factors used. Porter proposes three generic strategies: cost leadership, differentiation and focus. Cost leadership strategies are deeply embedded within construction, largely because firms frequently struggle to differentiate their products. More recently, there is evidence of some companies adopting a ‘focus’ strategy by concentrating on particular market niches with a view to providing excellent services to a limited clientele. However, the assumption that such strategies are mutually exclusive has been repeatedly challenged in the literature. Furthermore, Porter notably offers little advice on how organizational resources are to be aligned in the effective implementation of the adopted strategy (Connor 2003; Flint 2000; Klein 2002).

Within the strategic management literature, the term competitive advantage remains ambiguous and is frequently criticized for being divorced from context. Competitive advantage is seemingly a relative term that defies universal definition. Whilst the discourse of competitive advantage remains attractive, there is little agreement on what it means in operational terms (Connor 2003; Klein 2002). The broader community of strategic management researchers are highly critical of Porter’s perceived lack of precision (Connor 2003; Flint 2000; Klein 2002).

The continued ambiguity of the discourse of competitive advantage has profound implications on the adopted managerial practices (Thomas 2003), particularly, in the UK construction industry. The narrative of competitiveness discourse mobilized depends in part on the vested interests of different institutionalized groups. Managerial practice in construction can be categorized into identifiable constituencies (assembly of people, materials and practices that are governed by power, social relations/interactions, material practices, institutions and rituals, beliefs and values and discourse) (Thomas 2003) and sub-constituencies of interests as ascribed by industry participants. These competitiveness constituencies can be broadly identified as: (i) construction academics; (ii) construction consultants; (iii) the policy makers; (iv) construction practicing managers; and (v) clients. Given the heterogeneity of the construction sector, the last two categories are likely to be broken down into several sub-constituencies (Elmualim *et al.* 2006).

Within the domain of public procurement, emphasis has switched away from competition towards partnership. Current notions of 'partnering' and 'collaborative working' are indicative of this same shift in discourse (Egan 1998; Latham 1994). The supposed dichotomy between competition and collaboration/partnership however continues to attract much debate within both the public and private sectors (DTI 1998; Egan 1998; Karlberg 2004). The distinction between competition and collaboration is something of a red herring. Firms seek to engage in collaboration as a means of securing competitive advantage, i.e. they seek collaboration as a means of securing long-term returns. Clients are likewise attracted to collaborative relationships on the basis of the alleged benefits of innovation and continuous improvement. Paradoxically, effective collaboration can therefore make construction firms and clients more competitive. Similar arguments apply throughout the supply chain, although there is frequently a significant inertia to be overcome before firms can switch to relational contracting. It must also be recognized that firms frequently have to operate collaboratively and competitively at the same time, thereby eroding any prospects of an associated 'culture change'. A further complication is introduced by the fact that some firms espouse the rhetoric of collaborative working whilst continuing to behave opportunistically.

MUTUALISTIC AND ADVERSARIAL RELATIONSHIPS

In today's western liberal culture, competitiveness and conflictual relationships are ubiquitous cultural practices that are hegemonic in nature serving the interests of few. Such competitive and coflictual relationships are becoming the norm. In conventional wisdom, such relationships are inevitable expression of human nature (Karlberg 2004). According to Karlberg (2004), "throughout the contemporary public sphere, competitive and conflictual practices have become institutionalized norms. Indeed, contest models of social organizations and protest models of social change have become so ubiquitous that they tend to appear normal, natural and inevitable to those raised in western-liberal cultures." It is further argued that the norm makes it difficult to envisage alternatives (Karlberg 2004). To advance collaboration through mutualistic relationships require understanding of power sharing and distribution amongst individuals, across organizations and society at large. Indeed "in the long history of mankind those who learned to collaborate and improvise most effectively have prevailed" (Darwin 1859). Our existence as human beings will depend greatly on mankind to act together, though we might be thinking differently (Hofstede 2001). Archaeological and anthropological research suggests evidences of both modes of behaviour as two strands woven in the human culture. The paramount questions are; is the culture of contest and protest a reflection of human nature? do humans have the potential for either adversarial or mutualistic behaviours? What are the implications? Which culture promotes social justice and ecological sustainability?

Adversarialism

Adeversarialism is the pursuit of mutually exclusive interests by individuals or groups working against one another. Adversarialism appears in the form of contest, competition and confrontational relationships. According to Karlberg (2004) "though not all of adversary practices and forms of expressions may not be problematic, these forms of cultural codes are maladaptive, maladjusted and maladroit". Adversarialism creates a division between winners and losers.

Mutualism

On the other hand mutualism is the pursuit of mutually inclusive gains by individuals or groups working with one another. Mutualism enhances the chances of all members of the group to have the benefit of being winners, though the sense of winning might not be of a tangible form. Many schools of thoughts such as feminism, systems theory, ecology and environmentalism, communication theory, and alternative dispute resolutions advocate the vitality of mutualistic relationships to advance human progress. However, mutualisim is difficult to evaluate and to a greater extent is being marginalized because of the norms and therefore appear naive and idealistic (Karlberg 2004). To fully appreciate the benefit of the application of mutualistic relationship in real cultural communities, there will be a stringent need to have all embracing vision established through the understanding of structures, practices, institutional structures and strategies and collective decision making processes.

Tripartite axiological system

Construction organizations are shaped by divergent objectives and specific interests of different individuals, groups or departments. Each one with their own power base and discourse to legitimize their interest to the wider organization (Hardy *et al.* 2000). This specifically identifies the fragmentation of the construction industry as a whole and organizations operating in the construction market. Hence, the construction organizations can be described as pluralistic organizations that are characterized by multiple objectives, diffuse power and knowledge based work processes (Denis *et al.* 2007). According to Denis *et al*. (2007), pluralistic organizations throw three types of problems at those who want to promote concerted organizational actions; Individual autonomy that is associated with a diffusion of power and emphasis on knowledge-based work. Pluralistic organizations endeavour to provide a broad scope for individual action, encouraging local development and flexibility. This can become a barrier to the integration and coordination of the organization as individuals have the freedom to dissociate from the common objectives of the organizations. The second problem is the "inflationary consensus". Under a diffused power system, in practice, building a consensual decision may be achieved at the expense of realism. The third is that decisions and strategies are produced by the same people and processes which can result in producing a various layering of structures (Denis *et al.* 2007).

In any construction project individuals are required to make decisions in relation to other parties in the project. These decisions might be enacted in a mutualistic or adversarial manner to promote the interest of the whole entity or all one's self or organization limited interest. Those individuals are part of the organization and part of the society as a whole. Figure 1 shows this tripartite axiological system showing the interaction between society, firms and individuals.

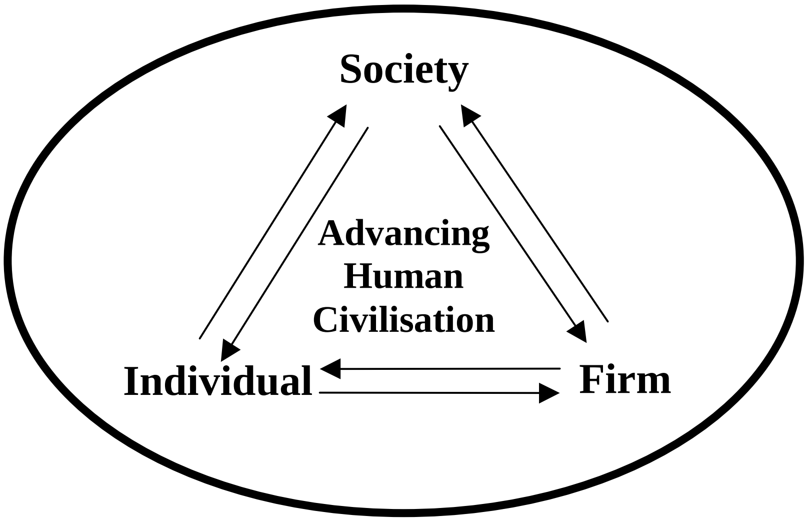

Figure 1: The tripartite axiological influences

This system is inherently an "Irreducibly complex system" (Karlberg 2004). It is evident that there is interplay between psychological and sociological behavioural dynamics (Lips-Wiersma 2002). “Psychological theory is fundamentally concerned with constellations of personal beliefs, attitudes and attributes and based on the assumption that individuals potentially have a moderate degree of destiny or control in their career” (Lips-Wiersma 2002). While sociological theories emphasizes the role of the environment based on the assumption that reality is socially constructed and institutionally influenced, such as culture and structure, play an important role in shaping personal behaviour, experiences and opportunities. Individual shared stories showed the duality of psychological and sociological influences and highlighted a wide range of relationships and interactions. There is an assumption that in changing oneself one can exert influence on their organization and hence the proposition of one can change the world. Likewise, individual choices, decisions and behaviours are greatly influenced by organizational structure and culture (Lips-Wiersma 2002).

In attempting to fully understand the drivers of mutualistic or adversarial behaviours, a different but complementary perspective is needed. This perspective is the notion of this paper. It is argued that to understand the model of adversarial behaviours in construction and advance mutualistic relationship, a perspective of psycho- structural and socio-structural is needed. This perspective further can be enlightened by understanding power and it is distribution. Such a joint perspective helps shed lights on the reasoning underpinning adversarial behaviours.

PSYCHO AND SOCIO-STRUCTURAL PERSPECTIVE

Culture has a complex and different meaning and shades (Hofstede 2001, 2003). It is a collection of systems of representations, meanings, beliefs, and other ideological variations among a particular social groups (Hofstede 2001). It encompasses political, economic, legal and other structural variations among social groups (Karlberg 2004). Culture can be seen as social heritage, a phenomena that is socially learned or constructed, relatively fluid and variable between populations and across generations, and hence there is a infinite cultural representations (Hofstede 2001). At an organizational level culture is the collection of relatively uniform and enduring values, beliefs and customs, traditions and practices that are shared by an organization's members, learned by new recruits and transmitted from one generation of employees to the next; it is the way we do things around here; the wary we interact; and the way we cooperate or compete. Hofstede (2001) refers to the mental programming of humans that is physically is determined by the brain cells. However, as it is difficult to observe these mental programmes physically but are observed through humans behaviour (Hofstede 2001). According to Hofstede (2001), every person's mental programming is partly unique, partly shared with others at the three levels of individual, collective and universal.

In the broadest sense culture is the entire social heritage of a community including material, ideological and structural expressions. These contingent expressions can be socially learned or constructed. For example our need to eat or drink are innate characteristics of our human nature, however, all forms of our tastes in food to the diverse ways of producing and distributing food are expression of our human culture. Indeed, and according to anthropologist Clifford Geertz "our capacity to speak is surely innate; our capacity to speak English is surely cultural" (Geertz 1973). The interplay between human nature and culture is well established as our need for culture itself is an innate characteristics of human nature. Hence the distinction between nature and culture is very subtle and very complex.

Having said that, the distinction between natural and cultural practices is of paramount importance in the study of managerial practices in construction. As adversarial practices in construction have been internalized, they are then represented as natural and inevitable to those who have internalized them. The prevailing assumptions are that adversarial practices are, as commonly argued, part of the fundamental make up of human nature as we are intrinsically selfish and aggressive (Hofstede 2003). However, Karlberg (2004) suggested such assumptions are not only misinformed but socially oppressive and ecologically unsustainable and that there is a need in establishing norms to regulate human nature (culture).

Cultures are not monolithic entities and that processes of physical and cultural evolutions are not distinct and nor sequential. The fundamental issue is that cultural practices can be internalized and therefore appear natural, inevitable and impossible to change. In his study, Hofstede (2001) found variations of individual behaviour across the globe. These behavioural variations where an individual can be cooperative or competitive depends on power distance (relating to human equality), uncertainty avoidance (related to stress level in unknown circumstances), individualism versus collectivism (related to the individual integration into the primary group), masculinity versus femininity (related to the division of the emotional roles of men and women in society) and long-term versus short term that relate to the focus of people's efforts to the present or the future.

It is evident that to understand human behaviour one needs to appreciate the two levels of culture the socio-structural and the psycho-structural elements (Hofstede 2001, 2003). Socio-structural element of culture (the culturally contingent models of social organizations) deals with groups and organizations of society, relationships between labour and capital in a capitalist economy and between first and third world nations in a post-colonial world order. Changes are made by reforming underlying structures- making of laws and regulations (Karlberg 2004).

Psycho-structural dimensions of culture (understanding the contingent structure of the human mind) highlight subjective understandings of individuals. Changes here are by raising awareness, rethinking values or identities or reforming attitudes and beliefs (the subjective structure of the mind rather than the structure of social organizations). This can be appreciated in the early years of development of individuals mostly in childhood and youth. Although media campaigns for different age groups or specific groups can be used these days to achieve the desired changes (Karlberg 2004).

It appears that there is a need for a dual strategy. Individually humans have the potential for adversarial as well as mutualistic behaviour. The degree to which we realize either of these potentials is a function of the cultures we are raised within (Hofstede 2001; Karlberg 2004).

UNDERSTANDING POWER TO ADVANCE MUTUALISM

Hislop (2005) argues that one of the major criticisms of the majority of the mainstream management literature is the neglect of issues of power and conflict. Fundamentally, individuals and organizations in construction have inherent tensions built into them which unavoidably results in them possessing an, 'unequal distribution of power'. The uneven distribution of power results from the reality of the diversity of construction and hence participants in the processes are not necessarily equal. This uneven distribution of power creates potential conflicts in the processes of construction projects (Wild 2002). According Karlberg (2004), there are four distinct power distribution whether related to individuals or organizations. The first model of power distribution is power over or to have power driven mainly by culture of contest. This model of power distribution results in a state of inequality between parties coupled with adversarial relationships (see Figure 2). The second model of power distribution is assisted power which results again in a state of equality but might help to develop mutual relationships. The third model is a balance of power that results in equality between parties with probability of the parties resorting to adversarial attitudes. The fourth model is mutual empowerment or power with (mutualism). This model clearly advances mutualistic relationships on an equal basis.

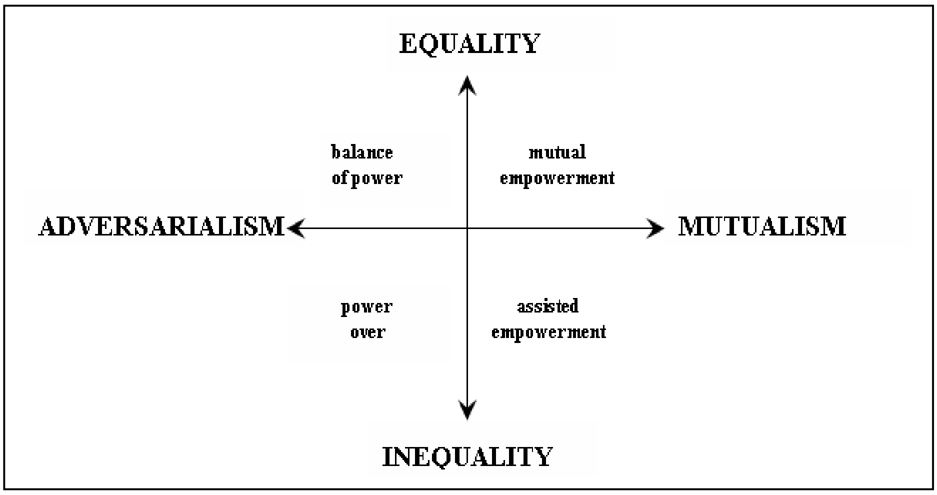

Figure 2: Power distribution and relationships (Karlberg 2004)

Indeed, the model of contest can be seen in our economic, legal and political systems. In academia, the Greek-based competition epistemological model of contest of ideas (intellectual contests) is viewed as the best way to generate knowledge by structuring its production as a contest between competing ideas. This assumption views human as aggressive and greedy by nature – “natural selection” (Karlberg 2004). However, cultural models of cooperation are seen as enablers for human to survive rather than aggressive impulses. “Rejecting the fundamentally self-interested and competitive understanding “*homo economus*”, economist expand the understanding of human nature as cooperative, altruistic and even self-sacrificing” (Geertz 1973). Such assumptions can also be seen in game theories and economics. Furthermore other schools of thoughts such Feminism, System theory, Ecology/Environmentalist and communication theories advocate the later models of culture, a culture of mutualism.

Feminism argues that aggressive and competitive structures serve as a structure for male domination. In feminist theory, empowering others is seen as a rewarding and gratifying activity. Women stress power as a capacity rather than domination (Karlberg 2004). This paradigm of thinking is complemented by System theory. System theory is a relational paradigm that characterizes the study of complex systems adapting a holistic or systemic focus that reveals the connections or interrelations within the system. It aims to understand the wholeness or interdependence of a system where the system is adapting to an organic view of the world/system. It further emphasizes the reality of increasing interdependence and the need for a movement towards post-hegemonic cultures (Karlberg 2004). System thinking requires that individual members of a system should be attached to the vital interest of the whole and not to hesitate to subordinate every particular interest for the sake of over-riding interests of the whole. In a world of increasing interdependency, the interests of the part are best reached by the advantage of the whole. As no lasting results can be achieved by any of the component parts if the general interests of the whole entity itself are neglected or marginalized by any of the parts. System thinking advocates an integrative power model. This integrative power model is seen as “the capacity to build organizations, to create families and groups, to inspire loyalty, to bind people together, to develop legitimacy” (Karlberg 2004). Such are the underpinning of the ecology/environmentalism models that provide an epistemological model for reconciling “oppositional” viewpoints, where the differing views are seen as complementary and necessary for the dynamic of the group (Karlberg 2004).

Another school of thought that promotes mutualistic relationships is communication theories. Theories of interpersonal communication suggest that adversarial modes are counterproductive within families, among friends and among co-workers. Individuals cannot afford to offend each other especially in long term relationships. Communication theory advances the interest of the group by developing a collective discourse through dialogue. Dialogue opens up the channels that “contribute to the thinking about an issue so that everyone involved gains a greater understanding of the issue in its subtlety, richness and complexity … an understanding that engenders appreciation, value and sense of equality. … Absent are efforts to dominate others because the goal is the understanding and appreciation another’s perspective rather than the denigration of it simply because it is different”(Foss and Griffin 1995).

In adopting such psycho and social perspective, as part of the discourse in construction, one can influence the thinking as through thinking, actions can be generated for genuine collaboration. This in turn will create a paradigm shift for collaboration to advance mutualaistic relationships in construction.

CONCLUSIONS

The construction industry is widely viewed as a fragmented and diverse industry. As it is a project-based industry, the delivery of construction projects requires the participation of various agents. Each agent comes with their own cultural values, modes of operation and interests. Such cultural values and interests produce a power distribution system amongst participants that leads to conflict and adversarial relationships. Adversarial relationships are strongly disapproved by all, particularly policy-makers. However, organizations within construction while espousing the collaboration rhetoric of the policy-makers, they exploit every opportunity to gain a competitive advantage over their rivals and other organizations in the supply chain.

This paper attempts to re-address the issues of collaboration and competitiveness in construction via different yet complementary approaches of psycho and socio structural study. This complementary approach seeks to discern the dichotomy of collaboration and competitiveness by understanding power distribution among social groups. Such an approach sheds light on the nature of power, its distribution and its influence on driving competitive or genuine collaborative behaviours as foreseen by individual, organization and society as whole. It is argued that our culture of competition has become the norm and that the norm makes it difficult for individuals and organizations to see other alternatives. Contests are being seen as normal and necessary models of social interactions and, hence, "normative adversarialism" has become the predominant strand in contemporary western-liberal societies. Psycho and socio structural approaches show that individuals are greatly influenced by their organizations. Both individual and organizations are influenced by the wider society in a very complex and intertwined tripartite axiological system. Individual humans are intrinsically and culturally programmed towards competitive and collaborative behaviours. It is argued that in the post-hegemonic society cooperation and mutualistic relationships will be best to serve the interests of the participants of construction projects delivery. Such a view is supported by various schools of thoughts such as communication theory, system thinking, feminism, and environmentalists groups. Competitiveness discourse is better seen as a mean for training or acquiring cooperative skills in order to advancing collaboration and mutualistic relationships in construction.

THE ‘PRACTICE TURN’ IN ORGANIZATIONAL STUDIES AND CONSTRUCTION MANAGEMENT RESEARCH

Mike Bresnen[1]

University of Leicester School of Management, University Road, Leicester, LE1 7RH, UK

The ‘practice turn’ in organizational studies has recently emerged as an important set of perspectives which has implications for understanding processes of knowing and learning within and between organizations. Consisting of a range of different approaches, it emphasizes the situated nature of knowing and learning in practice and offers an alternative to understanding human action that transcends the dualism of structure and agency effects on action. The ontological and epistemological underpinnings of a practice-based approach are assessed before attention is directed towards the implications for construction management theory and research and for an understanding of knowledge, learning and change in project-based organization.

Keywords: organizational behaviour, organizational analysis, organizational learning, practice-based perspectives.

INTRODUCTION

Within mainstream organizational and management studies, there has been considerable interest in recent years in ‘practice-based’ views of organization – particularly in the area of organizational knowledge and learning. In contrast to approaches that take a more abstracted or ‘commodified’ view of knowledge management, innovation, organizational change and learning (and which treat, for example, ‘knowledge’ as an object that can be shared, transferred and manipulated), practice-based theorists and researchers have focused attention instead upon what people actually do (thus, treating processes of ‘knowing’ as of central importance and interest) (e.g. Orlikowski 2002). Rather than beginning with theories abstracted from action, therefore, theory and research from a practice-based perspective takes a more inductive line, in which interest is directed towards the ways in which practices (and, through them, structures and systems) are constituted and re-constituted through the complex and situated use of a wide array of tools, technologies, objects, languages and bodies of knowledge that populate a domain of activity.

Although the ‘practice turn’ in organizational studies stems from a range of theoretical traditions (including structuration theory, activity theory, actor-network theory and ethnomethodology), there are common concerns and interests – for example, in exploring the constitution of action through localized practices; and in understanding how interaction is affected by the role of technologies and objects (Carlile 2004). Underpinning research in this area has also been a long-standing critical interest in the importance of power for understanding how practices are constituted and how they, in

[1] m.bresnen@le.ac.uk

turn, relate to broader social structures in which action is embedded (e.g. Foucault 1980; Giddens 1990).

Drawing indirectly upon research undertaken recently by the author into organizational knowledge and learning processes in project-based organizational forms (Bresnen *et al.* 2003, 2005a), this paper explores the applications of practice-based theorizing and research to the further development of construction management research, assessing in particular, the usefulness of such approaches for uncovering processes relating to, inter alia: the diffusion of innovation and 'best practice'; the effecting of organizational change within the industry; the effects of physical and other objects in mediating inter-organizational working relationships; and the effects of different 'professional' working practices on project team integration.

Although the paper takes a more theoretical than empirical line, it also takes the position that an emphasis on understanding practice and its relationship with theory is critically important in an age in which 'Mode 2' forms of knowledge production are considered vitally important (Gibbons *et al.* 1994), and where, in organizational and management studies at least, there is a perceived need to overcome the 'double hurdle' of academic rigour and practical relevance (Pettigrew 2001) and be involved in 'engaged scholarship' (Van de Ven and Johnson 2006). At the same time, there are important methodological implications for construction management research that emerge from an engagement with practice-based perspectives, not least of which is the importance it places on ethnography and more in-depth methods, such as observation.

THE PRACTICE TURN IN ORGANIZATIONAL STUDIES

Practice-based perspectives in organizational studies have emerged in recent years partly as a response to the long-standing problem in philosophy and social theory of the dualism that exists in the relationship between agency and structure as the basis of human action (e.g. Giddens 1990). Put simply, the problem of understanding action is whether one attaches primacy to the influence of individual freewill or to social structure as the basis of human behaviour. Differentiation in the social sciences between, in particular, psychology and sociology reflects this difference in emphasis between, on the one hand, individual cognition and agency and, on the other hand, social structure as the basis for action. Although these disciplines do attempt to meet in the middle (via the sub-discipline of social psychology), the recursive nature of the relationship between agency and structure is never fully resolved. So, for example, if social structures shape, if not determine, our behaviour, what part does agency play (or what part *can* it play) in the production of social order, the enactment of social systems and the development of social change?

Practice-based approaches are an attempt to transcend this dualism and overcome the schism between psychological and social approaches that lies at the heart of the social sciences by proposing the 'field of practice' as the appropriate point of departure for the study of human behaviour. Rooted in various philosophical traditions – including phenomenology, pragmatism and Wittgenstein's philosophy – the approach sees the social world as "a field of embodied, materially interwoven practices centrally organized around shared practical understandings" (Schatzki *et al.* 2001: 3).

A practice-based perspective therefore contrasts, on the one hand, with structuralist perspectives that emphasize the (determining) influence of social structure on action and the establishment of custom-like regularities (e.g. routines). Instead, practices are actively constituted and are more fluid and unfolding than more regularized routines (Schatzki *et al.* 2001: 6-7, 13). On the other hand, although there is more connection with individual action, practice-based approaches also contrast with more individualist perspectives (e.g. symbolic interactionism) by emphasizing the *embodiment* of cognitive capacities, not just the importance of cognitive abilities linked to reasoning and freewill. So, for example, practices, which can be minimally defined as ‘arrays of human activity’ are seen as “embodied, materially mediated arrays of human activity centrally organized around shared understandings” (Schatzki *et al.* 2001: 2). The emphasis is on embodied cognitive capacities and the importance of tacit shared understanding centred upon particular fields of practice. In turn, human agents and their identity are bound to practices (Schatzki *et al.* 2001: 11).

Given the scope offered by such a definition, it is perhaps not surprising to find that there is no single unifying practice-based theory or approach. Indeed, the range of perspectives encompassed is tremendously wide, including approaches such as phenomenology, hermeneutics and ethnomethodology, as well as the more specific theoretical frameworks of activity theory (Blackler 1993), actor-network theory (Callon 1985; Latour 1986; Law 1992) and Bordieu’s (1977, 1990) concept of the ‘habitus’. Despite this variation, however, there are important points of convergence, particularly in the emphasis placed upon understanding knowing and learning as unfolding processes centred upon practice (e.g. Orlikowski 2002). According to Nicolini *et al.* (2003: 3), organizational knowing is “situated in the system of ongoing practices of action in ways that are relational, mediated by artefacts, and always rooted in a context of interaction. Such knowledge is thus acquired through some form of participation, and is continually reproduced and negotiated; that is, it is always dynamic and provisional”. Crucially, therefore, practice-based approaches emphasize the fluidity of knowledge and learning and the difficulties of codifying knowledge and, thus, of representing knowledge of such practice (Shatzki *et al.* 2001: 8-9).

Inevitably, however, there are also important differences between practice-based perspectives, most notably perhaps in the emphasis placed upon the role of material objects. According to Schatzki *et al.* (2001: 11), practices are “materially mediated” nexuses of activity and, as such, objects play an important part in practice and in understanding processes of knowing and learning. Work on ‘boundary objects’, for example (Boland and Tenkasi 1995), demonstrates their importance in mediating communication within a joint field of practice and in providing the “tangible definitions” needed to allow knowledge to be shared or transformed (Bechky 2003; Carlile 2004). Work within an actor-network theory perspective, however, goes much further than this in proposing that objects themselves can play a part in propagating practices – effectively having agency and some impact upon behaviour through their role as ‘actants’ (Law 1992). Such a proposition has, of course, been subject to considerable criticism and debate. Nevertheless, it is clear that there exist important differences between practice-based approaches in the emphasis they place upon the role and impact of objects – both material and symbolic (Nicolini *et al.* 2003: 22).

There are also important differences in the emphasis placed upon issues of power and control within a practice-based perspective (Nicolini *et al.* 2003: 24). Although issues of power do tend to get acknowledged more in practice-based approaches, in those more concerned with integration within and across complex fields of practice (e.g. Brown and Duguid 2001; Carlile 2004; Wenger 1998), questions of control, hegemony and domination in social relations between actors tend to get downplayed.

In contrast, other perspectives that derive more from a poststructuralist perspective see relations of power as of central importance in constituting fields of practice through their impact on what constitutes knowledge, meaning, practice and identity. So, for example, systems of power within which social interaction is embedded have an important influence on practice through the mutual constitution of power and knowledge which, in turn, shapes meaning and identity through normalized conceptions of what constitutes practice (Foucault 1980).

Practice-based approaches have therefore become central to understanding organizational knowing, learning and change. In particular, work that draws upon concepts such as that of the 'community of practice' (Lave and Wenger 1991) has to some extent superseded more established IT-based approaches to 'knowledge management', in recognition of the highly situated nature of knowledge and learning and of the importance of social interaction through joint practice as the medium through which processes such as knowledge sharing, knowledge integration, knowledge creation and organizational learning take place (Brown and Duguid 2001). More generally, an understanding of the processes of knowing and learning as they occur through social interaction situated in practice and mediated through language and a variety of forms of material and symbolic objects has become an important part of understanding issues associated with organizational 'becoming', enactment and change (Orlikowski 2002; Tsoukas and Chia 2002).

THEORY AND PRACTICE IN 'MODE 2' RESEARCH

A focus on practice too dovetails with clarion calls from within the field of organization studies for research to relate more directly to the context of application, and to reflect more the needs of the range of stakeholders involved. Often referred to as a 'Mode 2' form of knowledge production (Gibbons *et al.* 1994), this represents a shift away from a form of knowledge creation that emphasizes the definition of problems by members of the academic community and the production of knowledge in stable, homogenous, university-based, disciplinary groups ('Mode 1'); towards a system in which knowledge is produced in the context of application by diverse, trans-disciplinary groups in decentred and dispersed networks of organizations.

Such a shift in emphasis has been criticized on the grounds of merely replacing one set of knowledge production values with another, equally politicized set of values (Grey 2001). Nevertheless, it does represent an important shift in thinking about the basis of knowledge about organization, the range of stakeholder interests and influences involved and, crucially important, the link between knowledge generation and the application of knowledge to practice (Starkey and Madan 2001). It also links in with wider debates within the field about the importance, particularly within the field of organizational/management studies, of overcoming the inevitable 'double hurdle' in research of academic rigour and practical relevance (Pettigrew 2001) and, more generally, with the renewed emphasis within the academy on 'engaged scholarship' (Van de Ven and Johnson 2006).

At other levels, however, the practice turn in organization studies points to a very different set of implications with regard to issues of research approach and method. At an ontological level, the suggested more relational, constructive, heterogeneous and situated nature of knowing and learning, combined with a more indeterminate view of supposedly fixed elements such as structure, knowledge and boundary not only sits very uneasily with the very idea of institutionalized patterns of 'knowledge production', but also brings into question any firm assumptions we may make about the aims of knowledge production and the range of stakeholders interests involved. As Nicolini *et al.* (2003: 27) put it: "From a practice perspective, the world appears to be relationally constituted, a seamless web of heterogeneous elements kept together and perpetuated by active processes of ordering and sense-making. Practices – including discursive practices – are a bricolage of material, mental, social and cultural resources". Whether or not one takes an approach that emphasizes relations of power and control, it is clear from this that knowing and learning are highly situated in practice, as well as continually constructed, re-constructed and contested.

A similar set of issues arises when one considers the epistemological implications of a practice-based approach to knowledge and learning. The strength of a practice-based approach is in getting close to practice and in exploring action in 'real time' – attempting to ground theory better in what it is that people actually do, rather than beginning with theories that are abstracted from practice. At one level, this would seem to dovetail well with the aim of grounding knowledge in experience and in effecting changes in practice where needed. An emphasis on situated learning and greater sensitivity to what is local and contingent would therefore appear to introduce a degree of social realism into the research process (via grounded theorizing) and a corresponding emphasis on action-centred and experiential learning.

At the same time, however, the methods implied by a practice-based perspective tend to rely more upon anthropological-ethnographic and sociological-participant observer techniques for conducting research. While such methods are by no means inconsistent with the level of engagement necessary for conducting action-based research, they do however proceed from very different assumptions from those methods more commonly used in applied business and management research (Bryman and Bell 2007). Not only do they take a much more qualitative, open-ended line for the study of organizational phenomena, they also tend to eschew any kind of privileged perspective on the issue at hand, in preference to taking as paramount the subjective position of those researched. In other words, such methods are not particularly well suited to, or even consistent with, an agenda for research that is determined 'top down' from a purely managerial perspective (even if that agenda is explicitly concerned with understanding subjective perceptions or attitudes).

Taken together, these characteristics of a practice-based perspective on knowing and learning in organizations suggest there are two main implications for management research – including that relating to the construction industry context. The first is that research aimed at understanding organizational processes from a practice-based perspective need to adopt methods that are sensitive to and suited to the highly situated, socialized and fluid nature of knowing and learning in practice. The second is that such research is not necessarily of a type that easily reconciles the needs and orientations of researcher and practitioner.

IMPLICATIONS FOR CONSTRUCTION MANAGEMENT

The above discussion suggests, of course, a number of key challenges in attempts to apply practice-based thinking to the context of the construction sector. However, it also suggests a number of ways in which application of practice based perspectives to the construction industry context can make not only a significant contribution towards understanding organizational processes within the sector, but can also contribute to a greater understanding of practice-based perspectives more generally.

One important area in which a practice-based approach can throw some significant light upon organizational processes is in the diffusion of innovation and 'best practice' within the industry and in related areas concerned with knowledge sharing/diffusion and organizational change. The prospects for innovation within the industry and for applying 'best practices' to construction management – particularly those drawn from the manufacturing sector – form a constant theme in discourse within the industry (e.g. Gann 2000). Yet, this co-exists with repeated observations of the difficulties of developing innovation and diffusing and implementing 'best practice' within the sector – difficulties that stem, at least in part, from the project-based nature of working (Gann 2001; Winch 1998).

Research recently undertaken has begun to explore in more depth and from a practice-based perspective the organizational aspects of project-based working that inhibit the spread and implementation of new management ideas, focusing upon dispersed organizational working and the effect that this has upon attempts to embrace and embed new working practices. So, for example, it becomes apparent that there are limits to knowledge codification in project-based settings that create important constraints upon project-based learning (Bresnen *et al.* 2003); moreover, that decentralized project-based working and project-based organizational forms do not necessarily provide a wholly suitable backdrop for the emergence and knowledge-sharing benefits of 'communities of practice' as traditionally conceptualized (Bresnen 2006a; Lindkvist 2005). Further research undertaken recently by the author suggests that the dispersed management practices that characterize construction and other project work create additional challenges in attempts to embed new ways of working (Bresnen *et al.* 2005a). These relate to the distribution of power/knowledge within project-based organization and the lack of synchronicity between new management initiatives and existing project management practices (Bresnen *et al.* 2005b).

All of these findings suggest there is some value in taking a more situated view of learning within the context of construction and in applying ideas that take a more politically-sensitized approach to understanding relations of power within communities and networks of practice (Contu and Willmott 2003; Swan and Scarbrough 2005). They also suggest that there are key aspects of the construction industry context that have important determining or constraining effects on processes of knowledge, learning, innovation and change which also have resonance with similar conditions found elsewhere (and which thus suggest the wider generalizability of construction management research). These contextual characteristics include the project-based, decentralized, transient and inter-organizational nature of project-based working in construction and relevant comparative settings include sectors such as film-making (DeFillippi and Arthur 2001) and biotechnology (Powell *et al.* 1996).

Another area in which innovation is important, and in which a practice-based approach can through some light upon the factors enabling and inhibiting change, is in the development and application of information and communication technologies to support project design and management processes. As suggested above, recent work has illustrated the importance of understanding the crucially important and complex relationship between new technology applications and social practices – for example, in the realm of 'knowledge management' applications (Bresnen *et al*. 2003). Attention has also been directed towards understanding the socially constructed, flexible and contested nature of the technologies themselves and how the fundamental malleability of the technology that results not only shapes, but also is shaped by, joint working practices (e.g. Harty 2005). The role of visual practices and associated artefacts has also been the subject of recent interests in terms of their impact upon processes of design (Whyte *et al.* 2007), including consideration of their effects as inscription devices upon sense-making and the politics of design (Bendixen and Koch 2007).

Taken together, such research also points to the crucial importance of objects – both material and symbolic – in mediating the social interaction involved in complex project design and construction processes (Bresnen 2006b). At the same time, however, research also ironically emphasizes the limiting effects of decentralized project-based working upon the use of boundary objects to provide internal cohesion and integration (Sapsed and Salter 2004). Consequently, not only might such research throw some important light on the roles of objects in mediating inter- (and intra-) organizational working relationships in construction, it also has important implications for understanding the role of objects in more decentralized and inter-organizational fields of practice that are typically associated with various forms of project – including, but not restricted to, those found in construction.

A further area in which a practice-based approach can make a very useful contribution to understanding construction management (and broader project management) processes is in understanding the effects of different working practices amongst members of the organizationally and professionally diverse team commonly found working together on construction projects. Again, the problem of inter-disciplinary and cross-organizational working involved on construction projects has historically – and almost ritually – been held up as a major factor leading to problems of fragmentation, poor communication and integration within the sector. However, the response has commonly been to apply a mode of analysis that invokes a more orthodox and unitary perspective that treats the problem of cultural differentiation as one requiring structural mechanism and/or efforts at cultural alignment to create better integration within the team (Phua 2004).

A practice-based approach, on the other hand, enables a deeper, more ethnographic exploration of the social processes involved in the developments of working practices – both those that derive from particular ‘epistemic cultures’ (cf. Knorr-Cetina 1999) and community-based activity (e.g. Gherardi and Nicolini 2003), as well as those that relate to the variety of practical predispositions that actors bring to joint activity – as signified in the concept of the ‘habitus’ (Bordieu 1990). Indeed, similarities and differences in predispositions towards practice within the project team may reflect the cultural and social capital that different groups bring to the relationship which, in turn, has an important bearing upon interaction and integration within the team.

The range of practice-based perspectives is, as already mentioned, wide. However, a few further general and tentative suggestions can be made on the basis of the range of perspectives signalled up earlier. An activity theory approach, for example (Blackler *et al.* 2000), would view the undertaking of a building project as a complex activity system, involving joint endeavour and a complex division of labour, where activities are mediated by language and a range of technological artefacts. Importantly, activity theory also recognizes the differing logics of action involved and the fact that such systems are disturbance-producing – an observation that will not only resonate with those familiar with the conflicts and differences found amongst members of building teams, but which also allows for the transformation of practice over time.

The application of actor-network theory or the ‘sociology of translation’ has already been implicitly referred to as underpinning much of the work on technologies as flexible artefacts (e.g. Harty 2005). Suchman’s (2000) work in this area, for example, shows how, in the specific case of engineering projects, it is possible to depict the task of building a bridge as a complex job of aligning expertise, motivations and interests amongst a range of human actors and non-human elements in a highly fluid stream of sense-making activity that constitutes and re-constitutes relations amongst interested parties in a highly variable and contingent way. Further insights from an actor-network theory perspective might come from understanding the ‘obligatory passage points’ that knowledge needs to pass through if it is to be accepted and legitimated (Callon 1985) and how these relate to the complex (multi-) institutional environment that provides the backdrop to much construction project working.

CONCLUSIONS

This paper has attempted to provide a broad overview of the ‘practice turn’ in contemporary organizational studies and to relate it to the context of the construction industry and, in particular, to the exploration of issues connected with innovation, knowledge, learning and change. In doing so, the paper has suggested an agenda for research in which several diverse perspectives within a practice-based approach might be deployed more fully to gain a greater understanding of construction management processes, issues and problems. At the same time, however, it is recognized that the ontological and epistemological implications of a practice-based approach pose significant challenges to established construction management theories and research methods. Nevertheless, it is proposed that applying such ideas presents interesting and worthwhile avenues for theory and research, as well as opportunities for generalizing insights gained about construction project organization to wider domains of practice.

Increased competitiveness in the construction industry requires the improvement of a construction company's capabilities to combine quality with economic and schedule aspects. Many studies and procedures in quality improvement focus on project quality improvement techniques and efficiency such as total quality management, value engineering, designability, contractability, constructability, operability, maintainability and other quality improvement techniques. This research focuses on constructability, which is the optimum use of construction knowledge and experience in planning, engineering, procurement and field operation to achieve overall project objectives. A case study was performed at an Indonesian refinery project, which applied the design and build type of contract. The case study aims to discuss and analyse the implementation of constructability innovation in the planning and design stage of the refinery project, focusing on optimization and improvement of pipe rack structure. The case study shows that the implementation of constructability during the planning and design stage increased the project performance and reduced the project cost.

Keywords: constructability, design and build, industrial plant, pipe rack, refinery project.

INTRODUCTION

Increased competitiveness in the construction industry requires the improvement of a construction company's capabilities to combine quality of materials and construction works with economic and schedule aspects. Many studies and procedures in quality improvement focus on project quality improvement techniques and efficiency such as total quality management, value engineering, designability, contractibility, constructability, operability, maintainability and other quality improvement techniques. Early involvement of construction knowledge and experience reduce the likelihood of creating designs that cannot be efficiently built, thereby reducing design rework, improving project schedule and establishing construction cost saving (Russell 1994).

In the US, the Construction Industry Institute (CII 1998) has developed 17 constructability concepts, which are grouped under the three main phases of project life cycle, viz. conceptual planning, design and procurement, and field operations. Those concepts were based on the experience of the owners and contractors represented on the CII Constructability Task Force, and the findings of researchers directed by the task force. The main purpose of the concept is to stimulate thinking about constructability and how to make it work. The second CII Constructability Task

[1] bambang.trigunarsyah@qut.edu.au

Force appended three additional concepts, two for the planning phase and one for the design and procurement phases (Russell *et al*. 1992).

The concept of constructability in the US (or buildability in the UK) emerged in the late 1970s. It evolved from studies into how improvements could be achieved to increase cost efficiency and quality in the construction industry. It is an approach that links the design and construction process. It became the subject of a number of research works in the 1980s (Sidwell 1996). Constructability is the capability of a construction project to be constructed. A constructability programme is the application of a disciplined, systematic optimization of the construction-related aspects of a project during the planning, design, procurement, construction, test and start-up phases by knowledgeable, experienced construction personnel who are part of a project team. The programme’s purpose is to enhance the project’s overall objectives (ASCE CM Committee 1991). Constructability is also defined as the ability of a project condition to enable the optimal utilization of construction resources (O’Connor 1986b).

The constructability concept was born out of the realization that designers and contractors see the same project from different perspectives, and that optimizing the project requires that the knowledge and experience of both parties be applied to project planning and design processes (Gibson *et al.* 1996). However, many owners, engineers, and contractors are still not aware of the potential benefits of improved constructability. Opportunities to reduce the schedule, improve the functionality of the final product and reduce costs are lost when construction is separated from planning and engineering (CII 1996).

Constructability input is needed because of the high technical complexity of today’s projects and the ever-increasing demands for faster and lower cost delivery of finished facilities (Fischer 1997). But collecting constructability improvement ideas is not an easy task. It requires perseverance on the collector’s part and often alternative thought processes for those providing the ideas. Designers are asked to think like constructors and constructors are asked to think like designers (O’Connor 1986a).

O’Connor (1988) found that the constructability is enhanced when innovative construction methods are utilized. The innovative construction methods refer to methods that are not generally considered common practice across the industry and which are often creative solutions responsive to field challenges. Innovative construction methods may involve:

1. innovative definitive sequencing of field tasks;
2. innovative uses of temporary construction material/systems;
3. innovative uses of hand tools;
4. innovative uses of construction equipment;
5. constructor-optional pre-assembly;
6. innovative temporary facilities directly supportive of field methods;
7. post-bid constructor preferences related to the layout, design and selection of permanent materials.

A new design and technology may be ‘a tool’ which the company can sustain in the construction industry. Innovation can provide the company with a competitive strategy to achieve the project and company objectives. But, on the other hand, construction innovations can produce certain risks associated with their use. The construction companies can use different approaches and strategies to effectively implement design innovation, based on their limited resources. Innovation is defined as a non-trivial improvement in a product, process or system that is actually used and which is novel to the company developing or using it (Marquis 1998, cited in Slaughter 2000).

The most informal constructability programme consists only of a set of checklists used by construction personnel to review design documents for completeness, errors and omissions. This programme is less effective than proactive formal programmes because construction knowledge and experience is provided in a reactive manner. Suggestions made by construction personnel often require redesign. The required redesign can contribute to an adversarial relationship between designers and constructors, as well as increase design cost and the project's schedule (Russell 1993).

Research findings (Tatum *et al*. 1986) suggested that the decisions made during conceptual planning have a major impact during the remainder of the project, particularly on the construction or the constructability of the project. The research indicated that the involvement of those who have construction knowledge and experience in this phase could provide information for critical decisions in the following three areas:

1. *Project planning*. Consideration of construction in the planning phase can result in two types of construction benefits: managerial benefit by having an efficient construction work plan as a result of sequences and schedules for completion of the design that better fit construction needs; and technical benefit by providing design concepts, criteria and approaches that make the final design easier to build.
2. *Site layout*. Consideration of the effect of the site layout on construction input can identify and avoid, generally with only minor changes in the original design concept, many types of construction problems, and thereby promote efficient construction.
3. *Selection of construction method*. Consideration of the construction method during the conceptual planning phase offers a major opportunity for improvement of constructability, thereby overcoming major technical challenges and avoiding high-risk operations. It is also a means of cost reduction.

This case study presents the implementation of a constructability programme within a refinery project, focusing on design process and changing innovation from the existing conventional design based on the constructability concept. Informal constructability programmes are developed to facilitate interdisciplinary communication between construction and design engineering personnel.

RESEARCH METHOD

The aim of this research is to study the implementation of constructability innovation at the project level. Early involvement of construction knowledge and experience (constructability aspects) at the planning and design phase will increase a project's performance (CII 1986; O' Connor 1987; Russell 1994). A case study was the preferred method of this research, as it studied contemporary events, but with the relevant behaviour unable to be manipulated (Yin 1994). This paper is a continuation study from Trigunarsyah (2004).

The purpose of this paper is to describe a process of technological innovation within the construction firm and to develop implications for increasing its rate. In this research, construction technology is defined as the combination of construction method, construction resources, work tasks, and project influence that defines the manner of performing a construction operation (Tatum 1987b). Innovation is the first use of technology within construction firms (Construction 1981, cited in Tatum, 1987b).

O'Connor (1987) performed the research and explored the CII constructability concepts for the design phase. The format for each concept is comprised of three parts: (1) statement of the concept; (2) discussion of the concept; and (3) specific application of the concept. The simplified concepts are focusing on (1) construction-driven schedules; (2) simplified design configurations; (3) standardization of the elements; (4) module/pre-assembly designs which facilitate fabrication, transport and installation; (5) accessibility and adverse weather.

Project performances are measured from constructability benefit parameters that are presented by Russell (1994b), where the benefit can be either quantitative or qualitative as seen Figure 1.

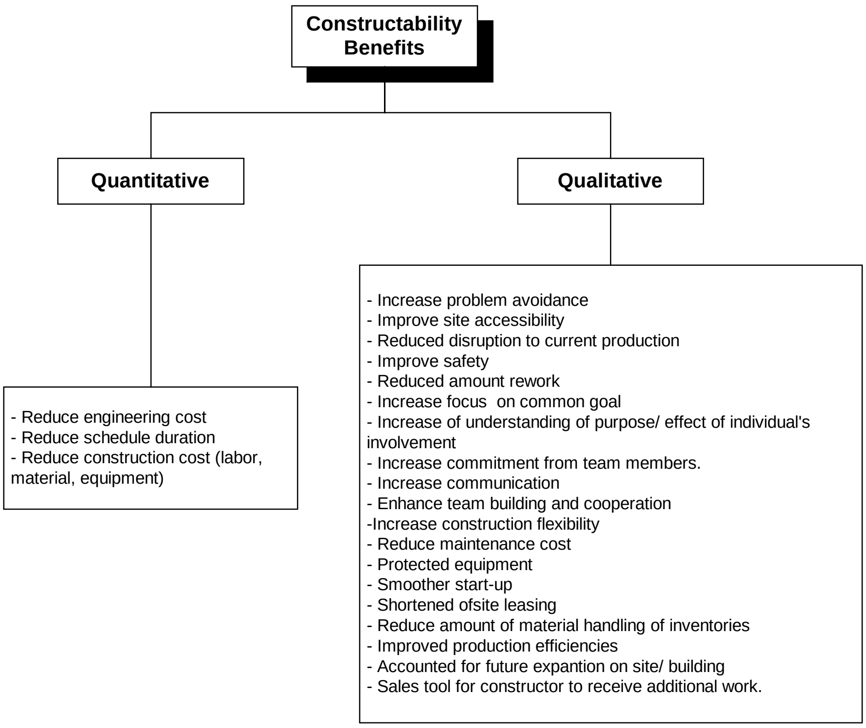

Figure 1: Framework for determining constructability benefit (Russell 1994)

Slaughter (2000) found the six stages of implementation for innovation often identified in theoretical literature and empirical studies are: (1) identification; (2) evaluation; (3) commitment; (4) detailed preparation; (5) actual use; (6) post-use evaluation, as seen in Figure 2.

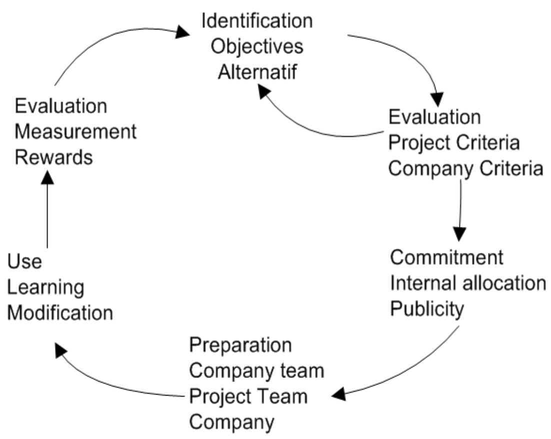

Figure 2: Implementation stages for innovation (Slaughter 2000)

A critical factor for the identification stage is the presence of a person within the company who is aware of potential solutions that might be applicable to the problem at hand (Slaughter 2000).

The parameters of constructability for this research are a combination of the implementation of CII constructability concepts at the planning (eight concepts), design and procurement (eight concepts) stages only, and focusing on specific application of constructability already studied by O'Connor (1987). The parameters are as follows:

1. early involvement of construction personnel (or knowledge and experiences);
2. overall project schedules are construction sensitive;
3. modularization and pre-assembly;
4. standardization;
5. simplified design configuration; and
6. construction method and innovation.

The constructability implementation checklists for this innovation were developed from constructability improvement classifications by O'Connor (1986b).

PROJECT DESCRIPTION AND BACKGROUND

The project selected for this case study was the engineering, procurement, construction and commissioning (EPCC) of the refinery plant in Balongan, Indonesia. The construction cost was about US$152 million and the contract duration was 25 months for mechanical completion and 27 months for operational acceptance, commencing in 2003 and completed in 2005. The contractor is a consortium of PT Rekayasa Industri (as a leader) and Toyo Engineering Corporation. The contract type is design and build.

PT Rekayasa Industri, an Indonesian state-owned construction company, which specializes in industrial-type construction projects, was selected as the case study. PT Rekayasa Industri's involvement in construction projects includes conceptual planning, engineering design, procurement, construction (or EPC) construction and project management services. This company has experience of projects of a size up to

US$250 million for EPC projects. Implementation of constructability improvement performed by PT Rekayasa Industry was based on the concepts of constructability developed by the CII.

The project was chosen as a case study because: it is a prestigious refinery projects conducted by a local Indonesian contractor; it is a design and built project, as most construction projects in industrial plant, was schedule driven, and most of the engineering activities overlap with procurement and construction, and some portion of the work is in potentially hazardous conditions; the diverse complexities of the scope of project, and multi-disciplinary involvement; the third writer was highly involved in the project during the planning and design stage and as advisor during the construction stage.

PROJECT CONSTRUCTABILITY IMPLEMENTATION

The awareness of constructability benefits can enable senior managers to make more informed decisions regarding the early involvement of construction knowledge and experience in the conceptual planning and design stage of this project.

Business considerations resulted in a scheduled total duration of 25 months. Based on the refinery plant average, a project of this size and scope is usually expected to take 30 to 36 months. Contractor project participants partially attribute the achievement of the project duration to the commitment to implementing the constructability concept.

During the bidding stage, the changing needs of the contractor and competition in construction competitive strategy purposes, led the contractor to propose the technological innovation alternative design based on the constructability implementation concept. This concept is primarily directed towards constructor organization. As discussed in the constructability concept file (CII 1986), the design and built contract method can enhance the constructability innovation, because the constructor preferences are identified early on, prior or during bidding stage, and are effectively treated during design and procurement and reflected in the initial issue of drawings and specifications. Under such ideal circumstances, 'design breakage' is minimal and the preferences are given full consideration by the designer with construction personnel.

This paper will discuss one of the constructability innovations that was proposed during the bidding stage. The innovation was: to change the steel pipe rack with concrete fire proofing into precast concrete pipe rack. The increase in steel price was one of the reasons why the contractor proposed this concept. A precast concrete pipe rack was a significant schedule and cost improvement concept incorporated early in the design effort. This precast concrete pipe rack concept was discussed with the engineers during the proposal stage.

Commitment for the precast concrete pipe rack innovation is needed from the parties responsible for achieving the objectives, such as contractor management, multidisciplinary design engineers, construction experts, site construction engineers, with approval from the owner, to reduce the degree of risk associated with the change. Once the precast concrete pipe rack decision was made, the multidisciplinary engineers worked closely to the precast concrete pipe rack concept and prioritized sequencing of engineering to ensure the idea could be carried out.

The company carried out incremental innovation to reduce risk and impact in the design and construction stages. The precast concrete pipe rack was developed by an organization with specific expertise, capability and control in implementation. The precast concrete pipe rack was evaluated with respect to the module it replaced and the risk associated with the design change within conceptual development design. The incremental innovation design process can be seen in Figure 3.

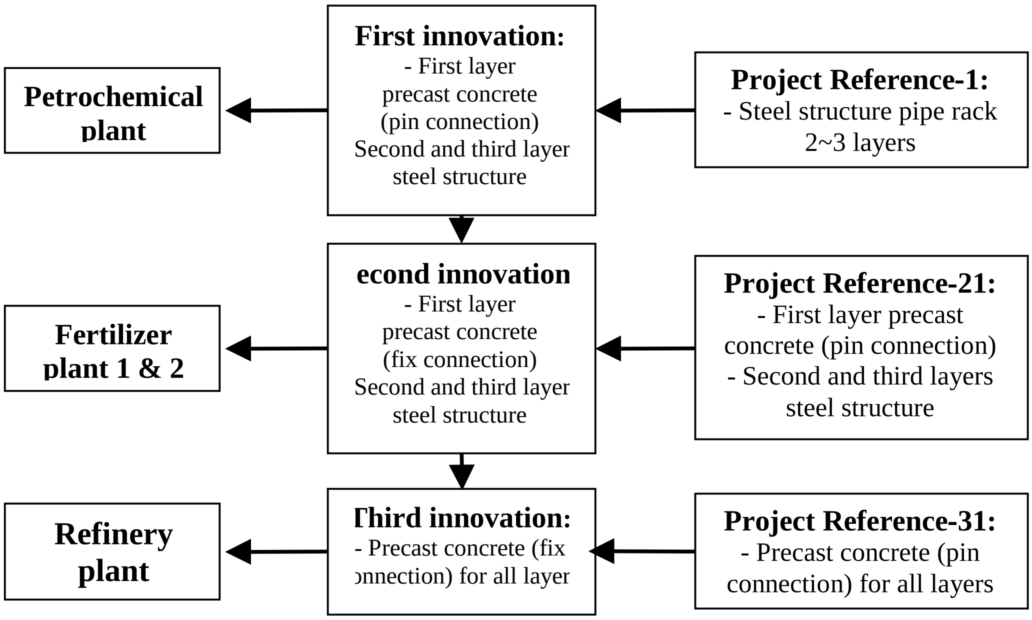

Figure 3: Innovation process for precast concrete pipe rack

The precast concrete pipe rack significantly affected the typical engineering and construction methodology of process designing from the process areas to the pipe rack. The design engineer had to assume and analyse a higher degree of risk associated with early sizing especially in piping and mechanical equipment layout drawings. There was an increase in design effort attributed to this practice due to the increased risk. The increase of rework can be avoided; however, as that problem can be anticipated early in the construction planning.

The safety and productivity were enhanced owing to the precasting work, thus the amount of work performed on scaffolding was reduced and medium cranes were used to erect the precast columns and beam simultaneously. The early site installations of the pipe rack columns also enhance safety and productivity, because the site activities can be focused on civil work only without any other disciplines involved. The complexity and risk of installation can be reduced.

The effective sequencing and repetitive activity in achieving enhanced the constructability. The benefits are particularly significant for the installation of the pipe rack itself, piping, electrical, instrumentation and mechanical equipment. Early installation of a precast concrete pipe rack can serve to minimize congestion and keep access routes open. The precast concrete method can also reduce the use of scaffolding.

Especially for the connection detail of the pipe rack the contractor hired a specialist from the university. The typical detailed precast concrete fix connection was filled with non-shrink cement grout.

The maximum length of column was 15 metres with maximum weight of precast concrete column 15 ton. For installation purposes, the main crane used had 60 ton capacity, and 30 ton capacity for the tailing crane. The cranes were used simultaneously with underground piping, above ground and mechanical equipment installation. Construction equipment shared by several activities increased the work productivity. The choice of precast method can also reduce the likelihood of delays in provision of utilities, and can improve the construction work environment especially with regard to weather conditions and the use of scaffolding.

During implementation of the project constructability innovation, the documented design process and implementation of the lesson learned for this pipe rack was described as follows:

1. Assign personnel as constructability champion to do the comparison study for specific precast concrete pipe rack.
2. Collecting the project lesson learned.
3. Preliminary concept design and construction method (technical pre-planning).
4. Brainstorming session with all project team and university.
5. Collecting the design and construction impact from multidisciplinary engineers.
6. Selection and distribution of priorities of the constructability decision (endorsed by management).
7. Transportation and procurement analysis.
8. Prepare the realistic EPC planning and schedule, based on limited resources.
9. Design concept approval from owner.
10. Optimization of design based on constructability concept.
11. In-house detail design.
12. Subcontracting of precast prefabrication and installation.
13. Presenting the detail sequence of pipe rack to subcontractor key personnel.
14. Controlling and monitoring of construction.

During detail design, all aspects of the constructability were analysed and exercised carefully. Fabrication method, transportation requirements and sequence of installation with three-dimensional analysis were prepared as seen in Figure 4.

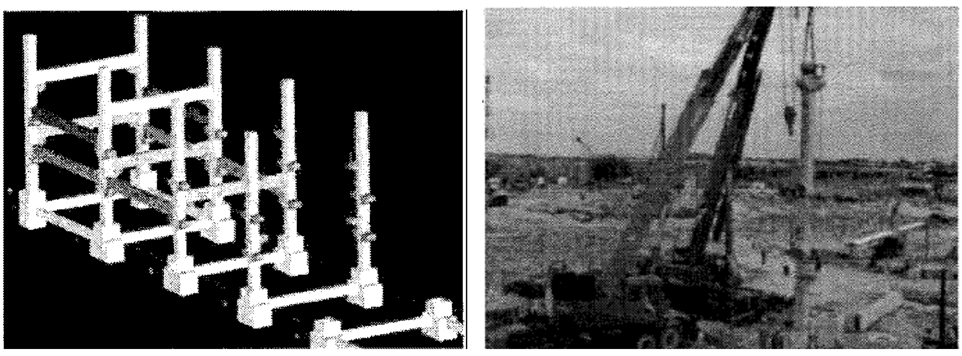

Figure 4: Precast concrete column beam: three-dimensional planning and installation

The installation of the precast concrete pipe rack was performed based on detailed sequence procedures already prepared during concept planning.

At completion of the project, the documented cost saving in this precast concrete pipe rack was 30.52%. The qualitative benefits of this constructability innovation also include reducing the schedule, increase of focus on common goal, increase in understanding of purpose/effect of individual involvement, increased commitment from team members, improvement in quality, site accessibility, safety enhancement, and better control of risk. Early efforts of construction activities can reduce the project schedule and congestion of the area during peak load of project. And the important factor is: the early efforts of constructability implementation can oblige the engineer to make the best efforts at each stage of the project. A comparison of major volume difference between the precast concrete and steel structure pipe rack is shown in Table 1.

Table 1: Major volume comparison of precast concrete and steel structure pipe rack

No.	Description	Quantity	Volume	
			Precast pipe rack	Steel pipe rack
1	Concrete foundation	M3	610	600
2	Concrete precast	M3	1770	—
3	Steel structure	Ton	—	710
4	Concrete fire proofing	M3	Included	240

CONCLUSION

This research has found that documented cost saving in this precast concrete pipe rack is 30.52%. The qualitative benefits of this constructability innovation also include reducing the schedule, increase of focus on common goal, increase in understanding of purpose/effect of individual involvement, increased commitment from team members, improvement in quality, site accessibility, safety enhancement, and better control of risk. Early efforts of construction activities can reduce the project schedule and congestion of the area during peak load of the project. And the important factor is: the early efforts of constructability implementation can oblige the engineer to make the best efforts at each stage of the project.

Lessons learned are indicated as primary factors in implementation of constructability. The case study shows that constructability implementation can result in innovation and improve the project performance. Early involvement of construction knowledge and experienced personnel, and standardization of design are the most influential factors of constructability implementation in increasing project performance and reduction of the project cost.

CURRENCY CONVERSIONS FOR CONSTRUCTION COST COMPARISONS: PURCHASING POWER PARITIES AND EXCHANGE RATES

Rick Best[1]

School of Built Environment, University of Technology Sydney, 702-730 Harris Street, Ultimo, NSW, Australia

The method used to convert construction costs to a common currency can have significant effects on the results obtained from comparative studies. The relationship between purchasing power parities (PPPs), both general and construction-specific, and market exchange rates with respect to the Australian dollar and three other major currencies was examined over the period 1990–2003. Trends over time were identified using linear regression and it was shown that there is little consistency in the relationship between general PPPs, average exchange rates and other indices. This highlights the need for reliable industry-specific conversion factors as currently there is no method available that can be shown to be more reliable than any other, and studies that do not include rigorous testing of the conversion approach used must produce questionable results.

Keywords: construction costs, exchange rates, international comparisons, purchasing power parity.

INTRODUCTION

Comparisons of construction industry performance, whether based on cost, productivity, projects or whole industry sectors, are notoriously difficult yet they are regularly attempted. A fundamental problem with virtually all such comparisons is the necessity to express all financial data (typically construction costs) in some common base currency, such as USD. Best and Langston (2006a, 2006b) show that the method used to make such cost conversions can have significant effects on the outcomes of comparative studies and their studies highlight the importance of using appropriate conversion methods if reliable results are to be obtained.

The aim of this paper is to extend that work by examining 10-year average exchange rates between several countries and comparing them to published purchasing power parities, both GDP level and construction specific, over a number of years in order to compare fluctuations in outcomes in respect of the various conversion methods used.

EXCHANGE RATES AND PURCHASING POWER

There is wide agreement that the use of exchange rates *per se* is not a sound method for converting costs (e.g. Goodchild and Griffiths 2004; Lafrance and Schembri 2002; ABS 2002; McKinsey 1995) as they are too volatile and are affected by a range of

[1] rick.best@uts.edu.au

influences that are not related to the relative value of currencies (e.g. Blake *et al*. 2006; Pilat 1996b).

Many argue that purchasing power parities (PPPs) provide a better basis for comparing financial data between countries as these conversion factors compare the value of monetary amounts based on the purchasing power of currencies in their respective countries and thus eliminate underlying differences in price levels (Al-adhadh 2002; Schreyer and Koechlin 2002; Ong 2003). It is often noted, however, that GDP level or general PPPs are not suitable for converting financial data at the level of individual industries (Pilat 1996a; Schreyer and Koechlin 2002; Stapel 2002; Goodchild and Griffiths 2004), and that there are few such industry-specific PPPs available.

Some construction-specific PPPs (CPPPs) are published but for a relatively small group of countries (European Union and OECD countries generally) and these are considered, for a variety of reasons, not to be very reliable (Vermande and van Mulligen 1999; Ive *et al.* 2004; Blake *et al.* 2006). The current method for gathering construction cost data for PPPs requires cost experts in each respondent country to price comprehensive bills of quantities for a number of ‘standard projects’; this raises many questions including the lack of familiarity with the BQ approach in many countries, problems associated with finding projects that are both comparable and yet representative of local practice, the expense that is incurred in hiring construction cost consultants to provide specialist knowledge (which results in only a single set of prices being obtained in each country) and problems of different interpretation of the pricing documents. The standard projects method is intended to gather out-turn costs (i.e. what the client actually pays) and therefore is designed to include mark-ups, labour/capital mix and other potential problems, but inconsistencies in pricing that are revealed by the extensive validation exercises that are routinely carried out by Eurostat (for instance) in pricing rounds for PPP production are one of the major reasons for the current distrust of the CPPPs that result.

While the search for methods that will produce more reliable CPPPs is ongoing (e.g. Walsh and Sawhney 2002; Meikle 2002), some (e.g. Langston and de Valence 1999) have applied other methods such as the Big Mac Index, published by *The Economist*, in attempts to address the problems associated with availability of suitable PPPs.[RB1]

Previous studies

One of the studies revisited by Best and Langston was carried out in 1993 (Lynton 1993); in that study a real office building project in the UK was priced, under several scenarios, in the US and the estimated costs compared to the actual costs of the UK project. The Lynton team used 10-year average exchange rates as the basis for currency conversion and then, using that as a starting point, identified Charlotte NC as a location where US input costs for a range of common building materials and labour were similar to those current in London at the time the sample project was built. In this way they attempted to eliminate price differences between the two locations, much in the manner that purchasing power parities are used to compare value between different countries with price differences removed (Schreyer and Koechlin 2002; Meikle 1990). The question that this raises, however, relates to whether the use of the 10-year average exchange rate is justified.

Best and Langston compared general PPPs to the 10-year average exchange rate (for GBP and USD) over the period 1990 to 2003, and plotted the available CPPPs against these values (Figure 1).

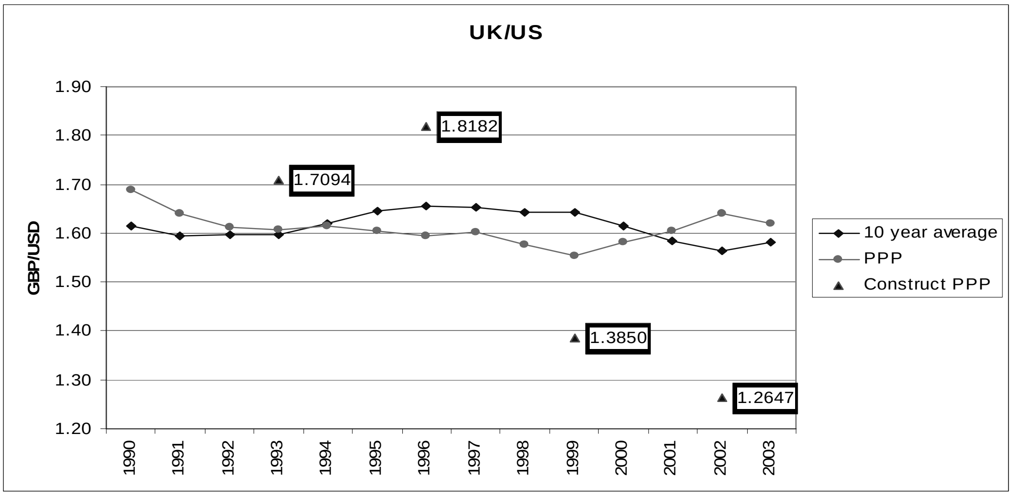

Figure 1: General PPPs, 10-year average money market exchange rates and construction specific PPPs (Best and Langston 2006b)

In 1993, the year of the Lynton study, the general PPP and the 10-year average rate were nearly the same, and the CPPP for that year was only marginally higher. This suggests that for that particular study the comparative costs reported should be sound as regardless of the method adopted to convert construction costs between the two countries the outcomes would be very similar. Furthermore the US costs were estimates and therefore subject to the normal variations of estimates hence small differences in the outcomes resulting from the use of different conversion factors were not considered to be significant.

By 2002, however, larger differences between the various factors are evident; while the general PPP was only around 5% higher than the 10-year average rate it was nearly 30% higher than the CPPP. Had the study been carried out in 2002 and CPPPs been used rather than either of the other options, the outcomes would have been quite different.

The results of two other studies (Flanagan *et al*. 1986 and DISR 1999) were shown to vary markedly depending on the conversion approach adopted (Best and Langston, 2006a). Similarly, in another analysis (Best and Langston 2006b) the use of general PPPs was examined and a reworking of the data reported in a paper by Xiao and Proverbs (2002) produced results notably different from those described by the authors of the original papers.

In the absence of industry-specific PPPs for the construction sector that are accepted as giving reliable comparisons of construction output between countries it may be that long-run average exchange rates may be a useful substitute. The following analysis compares 10-year average exchange rates to general PPPs (from several sources) and, where available, CPPPs and Big Mac indices for several developed countries, viz. the UK, US, Australia and Japan.

METHOD

This study compares conversion factors for Australian dollars and the currencies of three other developed economies: the US, the UK and Japan. The aim of the study was to determine whether there was any apparent consistency between the various conversion factors, and therefore if any one method or combination of methods could be said to produce more consistent or reliable results.

Sources of data

Ten-year average exchange rates were calculated using historical exchange rates (RBA 2007). The average for each year was calculated using either the last value for each quarter in that year, daily rates or monthly rates depending on data availability. Sensitivity tests show that annual averages vary little in relation to the method (daily, monthly or quarterly) that is used. The rolling 10-year average for any given year was calculated from the annual average exchange rate for that year and the preceding nine years.

General PPPs and CPPPs were retrieved from a variety of OECD tables (e.g. OECD 2002; OECD 2005) and the Penn World Tables (PWT 2006); historical Big Mac indices were taken from data files attached to Pakko and Pollard (2003).

The study period is the same as that used for the examination of the Lynton study (Best and Langston 2006b), i.e. 1990 to 2003. Construction PPPs are generally only published by the OECD at roughly three-year intervals while general PPPs are published annually.

As published PPPs express purchasing power relative to a base (USD or a group of countries such as the Eurozone) secondary PPPs between pairs of countries such as Japan and Australia were derived from the USD relative PPPs.

It should be noted that the regression lines shown on the following charts are used only to establish trends over the study period; they should not be interpreted as predictors of future movements.

Exchange rates

The AUD has lost value against all three currencies since 1981. The floating of the AUD in 1983 is reflected in significant drops through the mid-1980s but the general downward trend continued through to 2003 despite some movements against that trend, and some reversal of the trend in the last three years of the study period.

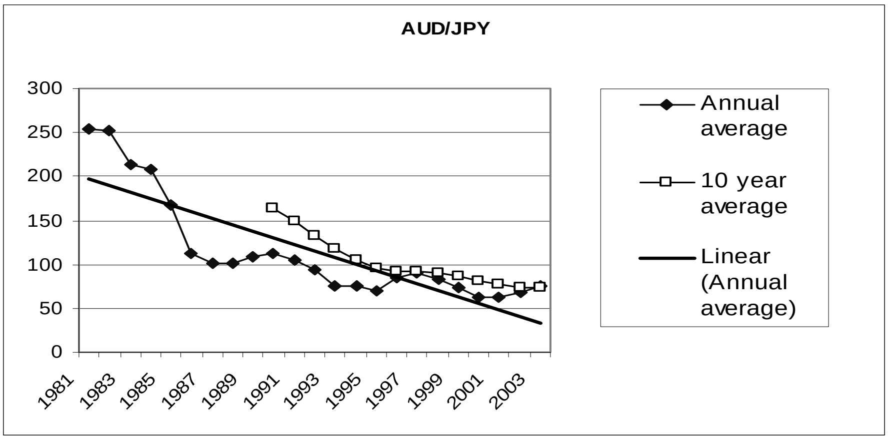

Figure 2: Historical exchange rates: AUD to JPY (RBA 2007)

Ten-year average rates (10YA) for the period 1990 to 2003 smooth out some of the fluctuations but the general downward trend is still evident. Note that the slope of the trendlines in the following three figures are not comparable due to different Y-axis scales.

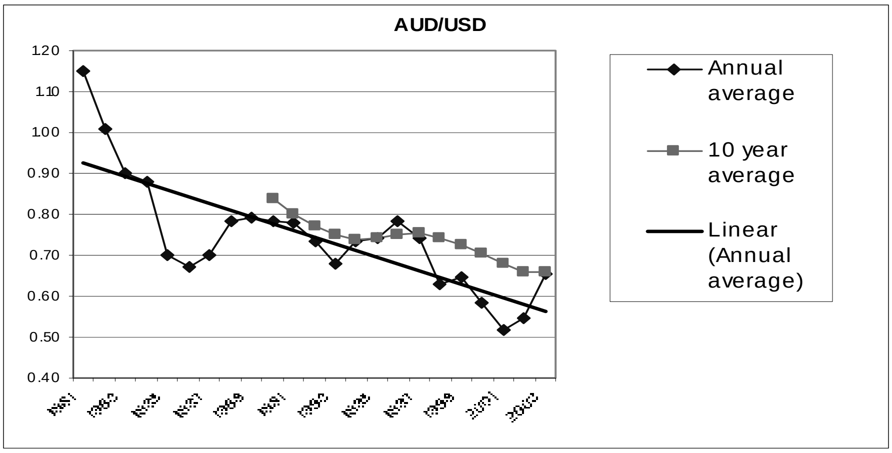

Figure 3: Historical exchange rates: AUD to USD (RBA 2007)

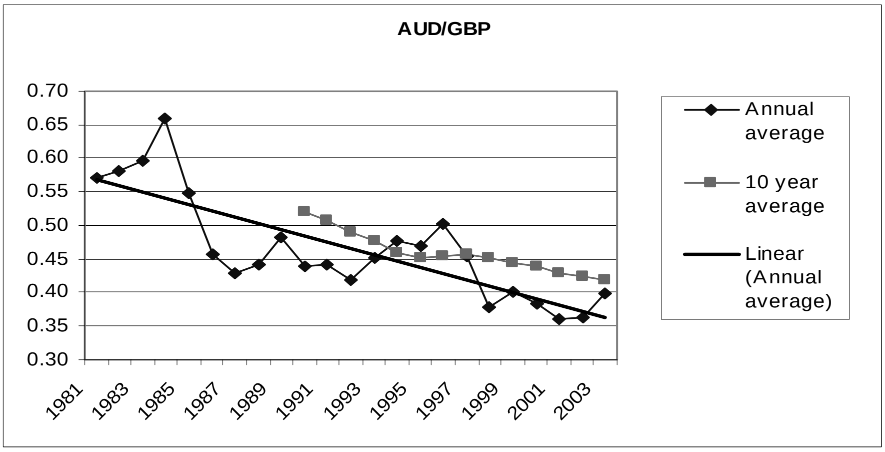

Figure 4: Historical exchange rates: AUD to GBP (RBA 2007)

Bilateral comparisons

The following three figures (Figures 5, 6 and 7) plot a number of conversion factors for the three currencies against the AUD.

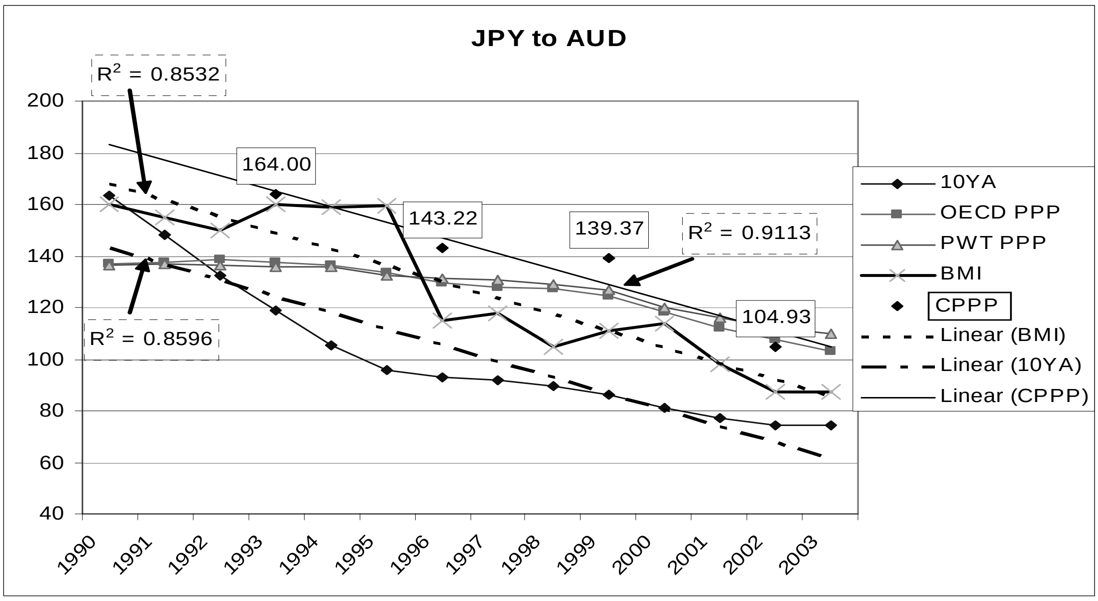

Figure 5: Conversion factors: JPY to AUD

Figure 5 shows the comparison between the Japanese yen and the Australian dollar. The graph prompts several observations about the relationship between the two currencies over the 14-year period and their relative purchasing power.

- The OECD and PWT PPPs are very closely aligned. This is to be expected as the PWT values for these countries are based on original OECD data; the other bilateral comparisons (AUD/USD and AUD/GBP) show similar alignment.
- The purchasing power of the JPY, based on general PPPs has risen by around 20% relative to the AUD.
- The 10YA exchange rate diverges quite substantially from the PPPs and highlights the problems of using exchange rates in comparative studies: while the relative purchasing power of the JPY has risen, the 10YA shows a considerably greater strengthening of the yen against the dollar in the period 1992–2003.
- The Big Mac Index (BMI) follows the same trend but for much of the study period shows more marked fluctuations from year to year.
- CPPPs show a similar trend, but these data are limited.
- Trendlines based on linear regression, all with strong r^2 values, show almost identical slope for the BMI, CPPPs and 10YA.

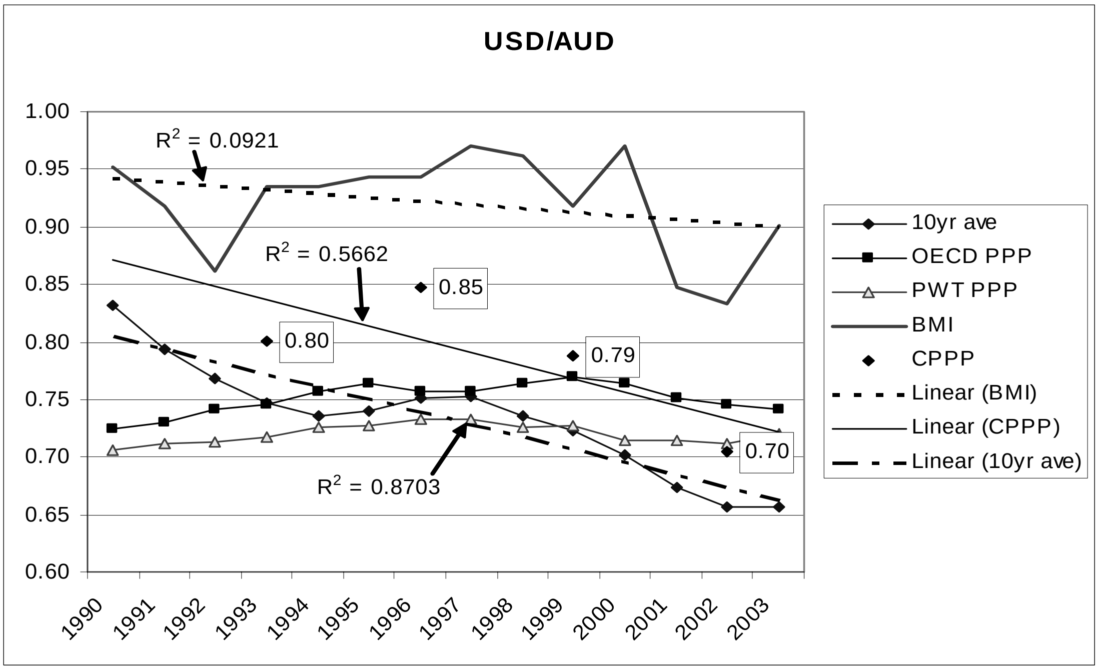

Figure 6: Conversion factors: USD to AUD

Figure 6 shows a similar comparison between the AUD and the USD.

- The OECD and PWT PPPs are fairly stable and reasonably closely aligned although they differ more than those in the previous comparison. The purchasing power of the USD compared to the AUD did not vary greatly from 1990 to 2003.
- The 10YA shows a steady strengthening of the USD against the AUD.

- While the Big Mac Index shows a similar downward trend to the 10YA the decline is not as marked and the BMI shows more marked fluctuations from year to year.
- CPPPs again follow the trend of the 10-year average and at similar slope.

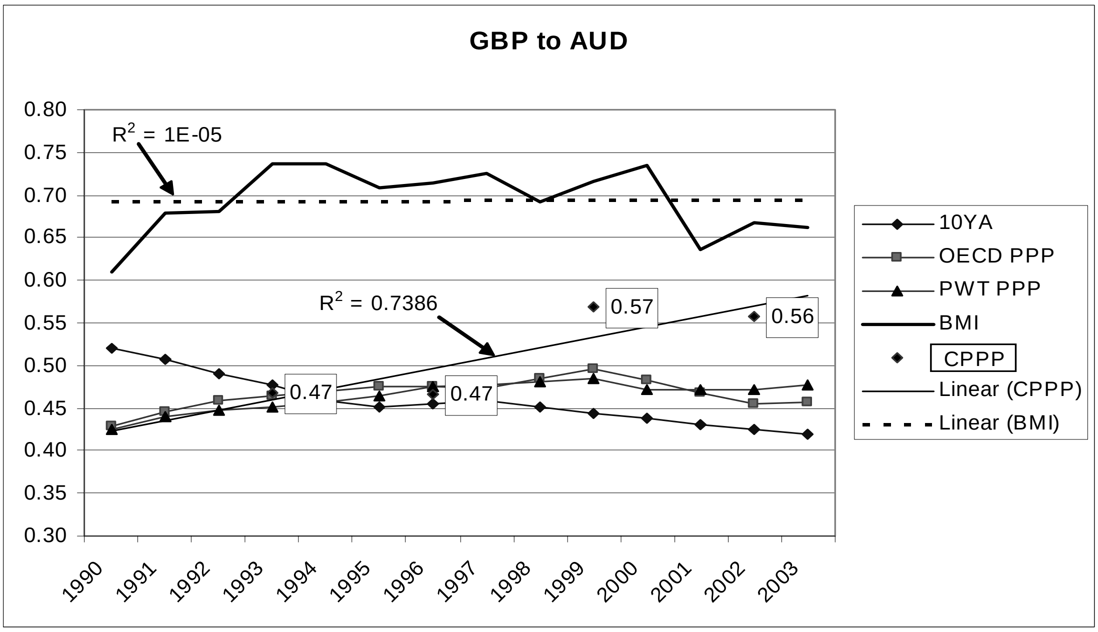

Figure 7: Conversion factors: GBP to AUD

Figure 7 shows the same factors for GBP and AUD. For clarity no trendline is shown for the 10-year average as it almost exactly on the plotline (R^2 = 0.9008).

- The 10YA and both general PPPs converge around 1993 and remain fairly closely aligned and stable through to 2003.
- The Big Mac Index, while suggesting that the AUD is considerably undervalued against the GBP and showing some sharp fluctuations from year to year, shows a nearly horizontal trendline over the 14-year period.
- CPPPs suggest an increase in the purchasing power of the AUD for construction.

ANALYSIS

The three bilateral comparisons tell a mixed story with some consistency apparent but with a number of notable inconsistencies also evident. While the AUD/JPY comparison shows that while numerical relativities for the BMI, CPPPs and the 10YA varied over time they showed nearly identical trends; the USD/AUD comparison showed similar but less closely aligned trends. The GBP/AUD chart, however, shows a different picture altogether with CPPPs moving upward while the 10YA moved down and the BMI showed short-term fluctuations about a nearly horizontal trendline.

There is little in this analysis to suggest that 10YA rates are a more or less reliable method for converting construction costs between countries than other possible methods such as PPPs or hamburgers. As Best and Langston (2006b) noted with regard to the Lynton study (see Figure 1) it was probably no more than good fortune that the 10YA, PPP and CPPP were all closely aligned in 1993. A similar alignment appears in the GBP/AUD comparison from 1993 to 1996 but, as Figure 7 shows, by

1999 and through to 2003 the CPPPs and the other indices (apart from the BMI) move well apart. In contrast, while the USD/AUD chart shows a similar alignment in the 1993–1997 period, and a similar divergence thereafter, the CPPPs move quite differently and show a trendline with a slope that matches that of the 10YA line very closely. The Big Mac Index, although showing some similar trends in the comparisons with JPY and USD, shows quite different implied exchange rates for all three currencies against the AUD.

DISCUSSION

Comparisons such as the AUD/JPY example here, that show numerical relativities varying quite substantially but show very similar trends over time, lend some support to the suggestion made by Langston and Best (2000: 37) that 'international comparisons between developed countries are … not sensitive to PPP adjustment'. That observation was, however, based on comparisons between only the BMI and OECD PPPs, and in that study, as is the case here, the UK was shown to be an exception. It should be noted, however, that as these are linear regressions the percentage change over time and between the different methods will still vary.

Generally speaking the CPPPs in the preceding figures show greater fluctuations than the other indices – this lends some support to the belief that CPPPs, as they are currently produced, are no more reliable than any other method as it is not clear whether these movements are caused by some specific factor such as cyclical variations, or if they are due to the inconsistencies in pricing that were discussed previously.[RB2]

Stapel (2004) advises strongly against the use of general PPPs for industry level comparisons and the BMI is not only much more volatile than the other factors but in two of the three examples shows relative currency values that are markedly higher than those shown by the other measures (with AUD/JPY the exception). It is such exceptions that reinforce the need for reliable construction-specific cost conversion factors as no currently available factor or method can be shown to be consistently better than any other.

CONCLUSIONS

The only sound conclusion that can be drawn from the foregoing analysis and discussion is that, as yet, there is no obvious, consistent result. It appears that reliable industry-specific PPPs are required as there is no great consistency across the other available methods. Current CPPPs, which are, in any case, only available for a limited number of (developed) countries, are treated with caution by most that are active in this area of research yet there appears to be no better alternative currently available; further work may, however, improve their accuracy and increase the range of countries that they cover.[RB3] Reliance on any single method will produce potentially unreliable results, and while it is not yet possible to determine if there is one 'correct' method it appears that some comparison of results obtained using a variety of methods is advisable.

While this study is limited to just three bilateral comparisons, with AUD as the common base, there is considerable diversity in the outcomes; further analysis is required, based on other currency pairs, to ascertain whether similar divergences are evident or if these results are peculiar to the AUD. Similarly further research is required to extend this analysis to developing countries.

THE WAY WE BEHAVE: PROPAGANDA AND ORGANIZATIONAL CITIZENSHIP BEHAVIOUR

Anita M M Liu[1] and Richard Fellows[2]

[1]*Dept. of Real Estate and Construction, University of Hong Kong, Pokfulam, Hong Kong*
[2] *Dept. of Real Estate and Construction, University of Hong Kong, Pokfulam, Hong Kong & School of the Built and Natural Environment, Glasgow Caledonian University, UK*

Today, firms are subject to a diversity of forces in the business environment that exert major impacts on performance objectives and targets. Many of the non-financial performance measures concern ethics of organizational behaviour, both inwards and outwards. Two particular behavioural considerations are organizational citizenship behaviour (OCB) and corporate social responsibility (CSR): OCB has an internal focus, whilst CSR looks outwards, primarily. The concepts of OCB of members of organizations, and organizations' behaviour in relation to perceived CSR is examined as components of more comprehensive citizenship behaviour. Construction projects are characterized as shifting, multi-goal coalitions based around a fluid power structure. That perception is examined from the perspective that the citizenship behaviours of participants may be manipulated through employment of propaganda to advance the ideology-driven agendas of certain (groups of) actors. The generic business environments within which project performances occur are, themselves, subject to propaganda-prone distortions. A particular difficulty is that the nature of propaganda renders it a covert activity with the consequence that the better it is carried out, the more difficult it is to detect and so, the paper, of necessity, draws attention to the distortions, engendered by propaganda, to which the behaviour of project participants, and those who seek to assess such behaviour, are subject.

Keywords: corporate social responsibility, organizational citizenship behaviour, propaganda.

INTRODUCTION

Today, firms are subject to diverse forces in the business environment that exert major impacts on performance objectives and targets. Construction projects are continuously and notoriously subject to diverse interests and pressures that seek to shape their processes and products. Such interests extend beyond the immediate project participants, corporate members and stakeholders to include many diverse individuals and groups – as epitomized in their being project coalitions (temporary multi organizations – TMOs) with changing memberships (e.g. Tavistock 1966; Egan 1998) and evolving goals dependent on ever-changing power structures rife with (potential) opportunism (Williamson and Maston 1999).

Financial forces focus on profitability, growth, cash flow (liquidity) and non-decreasing dividend streams. Whilst it may be argued that such financial measures constitute the primary performance imperatives for firms' survival, many of the non-financial performance measures constitute mechanisms for long term sustaining/enhancement of financial performance and concern ethics of organizational

[1] ammliu@hkucc.hku.hk

behaviour, both inwards and outwards. Two particular behavioural considerations are organizational citizenship behaviour (OCB), how individuals behave as organizational members, and corporate social responsibility (CSR), how the organization behaves as a responsible citizen of society. Both constructs are behavioural, concern ethics and, hence, are rooted in culture. Thus, an essential element in analysis of organizations is the context in which they operate, i.e. the nature of the society and the market including the members of the organization and its stakeholders.

Given that propaganda is “any association, systematic scheme, or concerted movement for the propagation of a particular doctrine or practice” (OED 2005), it influences the way people behave. The objective of this paper is to develop a conceptual model to examine propaganda in relation to citizenship behaviour of organizations – comprising OCB and CSR – within the context of construction.

CORPORATE SOCIAL RESPONSIBILITY (CSR)

Traditionally, CSR has a focus outward from the organization and concerns the actions of an organization towards the macro society. Macromotives – attributes that characterize individuals’ feelings and beliefs about others with whom exchanges occur – determine the potential for and operation of exchanges. The essential macromotives for relational contracts and social exchanges to be viable are trust, loyalty and commitment (Rousseau and Parks 1993).

Relations between organizations and society are “interwoven rather than being distinct entities” (Wood 1991), consequently, expectations of society impact on CSR. Social exchanges concern relationships involving future obligations that are unspecified (Blau 1964) and so generate expectation of returns in the future for contributions made. Social exchange contracts are based on long-term exchanges which are fair in the views of the parties, therefore, they do not require precise account-keeping but do require reciprocity of behaviour concerning the diffuse obligations involved (Graham and Organ 1993). Good faith and trust underpin the forms and timing of reciprocations and so, promote citizenship behaviour (Organ 1988) in the case of organizations in society.

Carroll (1979) contrasts ethical and philanthropic responsibilities by stating that the latter are what ‘should’ be done by the organization and adopts a model of CSR that has four component responsibilities: economic (profitability), legal (law-abiding), ethical and philanthropic (what society desires). The ethical responsibilities concern obligations beyond the legal requirements and involve doing what is considered to be right and fair – what society expects from a good (ethical) organization.

Over recent years, two sets of forces, privatization and globalization, are evident that countermand and modify citizenship. Privatization transfers the responsibilities for many social provisions (health care, education, pensions, etc.) (back) to individuals who then seek to obtain desired provisions (or effect insurance) through private means and organizations. Under privatization, rights are eroded and become wants, the satisfaction of which is subject to the operations of capitalist markets. Globalization reduces the importance and impact of territorial domains. Major governments and private organizations operate with increasing international influence, thereby reducing the sovereignty of, especially smaller/less economically powerful nation states. Important elements in the power gains of (private) organizations are lobbying of politicians and officers of governmental agencies, and contributions to funds of political parties, thereby distorting the operation of ‘enlightened self-interest’ (Smith 2000) and liberalism.

In a hypothetical perfectly ethical world, organizations would not require regulation; but, in practice, the statutory/legal controls (health and safety, town planning, environmental protection, etc.) act to secure minimum levels of ethical performance to protect society. In a less than perfect (‘real’) world, many businesses regard CSR as additional, discretionary activities that should be pursued only to the extent that ‘traditional’ (financial) measures of organizational performance are enhanced (Burke and Logsdon 1996), perhaps, especially, short term measures (Hutton 1996).

In delineating the boundaries of CSR, in terms of where relevant society lies, stakeholder theory asserts that an organization has responsibility to all persons (groups) affected (actually/potentially) by its actions – as in true professionalism. Further, relationships between organizational ethics and performance, and CSR and performance have been examined (e.g. McWilliams and Siegel 2000). Stevens (1994) discusses a variety of organizational motives for their use of codes of ethics: limiting legal liability, influencing employees’ behaviour and image building. Such codes represent documented statements of corporate values and norms and so, to be effective, must be communicated clearly. For many corporate statements, communication of meaning is notoriously problematic as the statements tend to be strategic and, hence, too vague for (immediate) operation – interpretation is necessary, which involves scope for flexibility.

The effects of propaganda are important to the study of CSR. Hence, it is worthwhile examining the effects of communication means and how propaganda impacts on people’s interpretations and judgements.

ORGANIZATIONAL CITIZENSHIP BEHAVIOUR (OCB)

Citizenship is rooted in relations between individuals and the (nation) state. Eriksen and Weigård (2000: 15) note that Aristotle (1992) considers citizenship to be the “right to participate in the public life of the state, which was more in the line of a duty and a responsibility to look after the interest of the community” – a citizen performs actions underpinned by a sense of duty of what is right and what is wrong.

Morals concern judgements of what behaviour is good/bad, right/wrong. Thus, values are central to the issue and context dependency must be addressed – a reflection of the cultural dimension of Universal-Particular (Trompenaars and Hampden–Turner 1997). Can any action, belief etc., be good or bad, right or wrong universally? That is not to dismiss objectivism but to acknowledge the pluralism of human existence. Hinman (1997) distinguishes morals as first order beliefs and practices about what is good and what is bad which guide behaviour, and ethics as second order reflective consideration of moral beliefs and practices. Rosenthal and Rosnow (1991: 231) note, “ethics refers to the system of moral values by which the rights and wrongs of behavior … are judged”. Snell (1995: 155) notes that moral ethos, which can be a strong force to encourage or constrain action, is, “the social climate predisposing members of an organization toward adopting and enacting some particular ethical standards and deflecting them away from others”.

Rokeach (1972) regards values as signifying enduring beliefs in particular ways of behaving or preferences for states in the future. That raises questions of (1) whose values are to be employed in determining the standards and related issues requiring people to exercise judgement in the business context, as well as (2) how do values impact on one's behaviour in the context of an organizational citizen?

For instance, construction project TMOs comprise many stakeholders who have diverse values, interests and, hence, operational objectives. While such pluralism may be helpful, it articulates the ethical question of whose values (should) apply. Are the values to be applied on a project the result of cognitive integration and agreement or due to evolving dominance of the (financially) most powerful?

Generally, OCB is behaviour in the execution of employment which is in excess of contracted/normal job performance and which is likely to contribute to long term success for the organization. Thus, OCB contributes to organizational effectiveness, and efficiency, but is not subject to the organization's formal rewarding structure and is discretionary by individual employees. Organ (1988: 4) defines OCB as "behavior that is discretionary, not directly or explicitly recognized by the formal reward system, and that in aggregate promotes the effective functioning of the organization…the behavior is not an enforceable requirement of the role or the job description…the behavior is a matter of personal choice".

CONCEPTUAL MODEL OF CORPORATE BEHAVIOUR

CSR guides corporate behaviour (B_{corp}) in an outward-orientation towards fulfilling the organization's obligations to society.

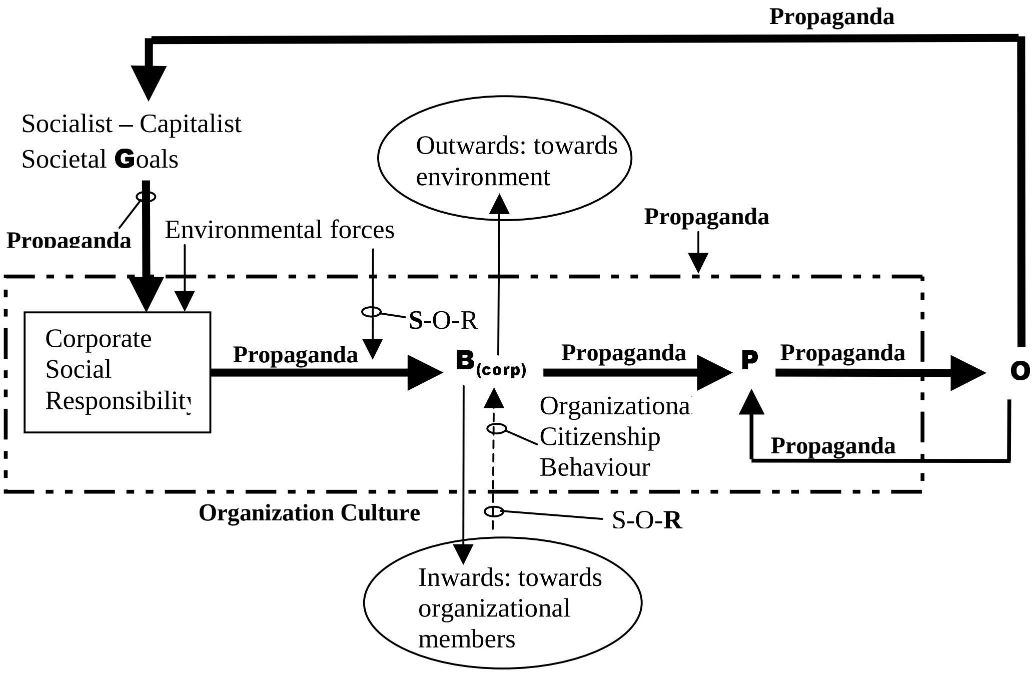

Figure 1: Influence of propaganda on behaviour (Key: S-O-R : stimulus – organism – response; $B_{(corp)}$: behaviour of the corporation; P: Performance; O: Outcome)

In the proposed model (Figure 1), CSR is envisaged as part of the response to the pressures of societal gaols according to the S-O-R (stimulus-organism-response) paradigm in organizational psychology. Environmental pressures (e.g. economic, legal, social etc.) act as stimuli on the organization and cause it to make a response.

Part of the response is to create a sense of CSR that may, finally, come to fruition in the form of a full response by bringing forth actions (or committing behaviours, B_{corp}) in fulfilling the societal goals.

Societal goals may vary in situational contexts of, say, socialist vs. capitalist economies. For instance, the organizations are expected to fulfil more extensive obligations and duties for the good of society and community in a socialist country. In China, previously state-owned enterprises (SoEs) were undertaking huge CSR (housing provision etc.). In present times, the SoEs are transformed to become non-state owned in the legal context but the business funding, control and operating mechanisms have undergone minimum changes in many large organizations. Those mechanisms were designed to fulfil governmental socialist goals. If societal goals remain unchanged, and minimal modifications are made to the business models (e.g. economic resource allocation, governance structure etc.), has CSR been reshaped? Take the case of housing provision where the Chinese government used to provide major input; in the immediate transition from a command economy, society may not be expecting less from the government and the government is not entirely releasing 'control' to the market.

The conceptual model in Figure 1 is explained further in terms of a behavioural approach to organizational analysis.

Goal – Behaviour – Performance – Outcome (GBPO)

A conceptual model of behaviour-performance-outcome (BPO) is proposed by Liu (1999) for construction procurement. The act is the basic unit of behaviour in the act-to-outcome process (Naylor *et al*. 1980) and has two defining dimensions, the amplitude (total commitment to an act as defined by the amount of individual time and effort allocated to the performance of that act) and the direction (the specific kind of activity being carried out). Evaluation of the outcome of an act is dependent upon two sets of contingencies (Naylor *et al*. 1980): (1) performance-to-evaluation contingencies and (2) evaluation-to-outcome contingencies. Thus, it is conceptualized that the behaviours (B), or acts, lead to performance (P) to produce an outcome (O) to be assessed. Goal-directed behaviours result from the organization responding to the environmental forces, i.e. the organization sets its goals (as in strategic planning) and adopts appropriate behaviours in pursuit of those goals.

The resultant behaviour of the organization (B_{corp}) has two interdependent components, inward towards its organizational members and outward towards the environment/society. The former constitutes how 'corporate' treats organizational members and, in turn, members make their responses by committing actions/behaviours which reflect OCB (e.g. Organ's (1988) OCB dimensions of sportsmanship, civic virtue, altruism, courtesy, and conscientiousness.) The latter constitutes a response from the organization to the environmental forces by committing actions/behaviours to fulfil CSR.

Dainty *et al*. (2005) assert that project affinity, emotional attachments to the project (objectives/purpose) outcome, enhances how people work, especially their OCB, thereby fostering performance. However, since the project organization is a shifting multi-goal coalition, stakeholders' (diverse) interests necessarily affect the direction and effort (amplitude and intensity) of behaviours.

Propaganda

The concept of propaganda relates to propagation – the widespreading – of ideas etc. to stimulate a pervasive and particular response. Propaganda is "The systematic propagation of information or ideas by an interested party, esp. in a tendentious way in order to encourage or instil a particular attitude or response. Also, the ideas, doctrines etc., disseminated thus; the vehicle of such propagation" (OED 2005). Thus, propagation relates to securing ends rather than the objective correctness/justice of the notions which are propagated. In the proposed model (Figure 1), propaganda plays a pervasive role in the operation of the GBPO cycle.

Propaganda involves widespread communication, usually of doctrinaire style and content, with the objective of advancing the interests of the perpetrators. A usual perspective on propaganda is an endeavour to effect change; alternatively, it could be employed to reinforce a status quo. Hence, propaganda is a tool employed by the organization to indoctrinate its members (see Figure 1) to enhance organizational culture; propaganda is also used by society to foster goal setting in shaping the organization's CSR, including endeavours to overcome resistance.

DISCUSSION

Organizations in Western countries use mission statements and, more overtly, advertising and promotional 'catch phrases' to help create a favourable image. Signs on construction sites, however, tend to be relatively factual in providing information about what is under construction and the identities of the major participants. In less market-developed societies, such as mainland China and other command economies, notices on construction projects are quite different in purpose and content. Slogans are paramount. The (recent) social tradition is that all policies and initiatives, including construction projects, are led by a slogan that serves to announce the great value/purpose of the project and so, serves to foster acceptance of the project, motivate workers on it and promote it amongst potential users. Such slogans continue the central place of slogan-based propaganda, which has served government of such societies for some time to help effect and direct the focus of information dispatch; however, increasing access to global media and other propaganda techniques is rendering the displaying of signs and slogans of less effect – television advertising and internet access, despite 'firewalls', reach huge audiences rapidly and to greater effect.

Common propaganda techniques involve language distortions of various types – including the use of generalized statements that leave the recipient to 'fill-in' the picture by envisaging specifics. Many other forms exist to inculcate beliefs and consequent actions (if only of non-resistance), including implications of general beliefs/knowledge, alienation of non-conformists, and threats of many forms.

The construction industry is towards the forefront of several changes/initiatives – e.g., environmental impact reduction and privatization. In UK, the majority of projects for the, now much reduced, public sector are carried out under formal private finance initiative (PFI) arrangements – a form of concession contracting, design-build-finance-operate (DBFO). PFI constitutes a particular form of public private partnership (PPP). At face value, partnership sounds, 'just what the industry needs', involving teamwork, cooperation, collaboration, dispute avoidance, etc., but, partnership is not partnering although, in the context of PPP, it is commonly portrayed as such.

In the realm of propaganda, partnering is, essentially, a trust-based, collaborative, and enduring relationship between construction project participants. The objectives of partnering (previously teamwork) are to enhance returns to the participants through improving project management performance – i.e., enhancing efficiency of supply. If partnering has such extensive benefits as claimed by its advocates, it is amazing that it remains unusual in practice and operates only partially in most instances. That, of course, could be an issue of differing definitions or evidencing that it is inappropriate for construction. An acid test could be whether its advocates practice full partnering themselves. According to Green (1999) that is not the case and further, powerful anecdotal evidence supports Green's findings. Green notes that major clients who are leading advocates of partnering in construction conduct far more 'traditional', self-interested practices in their core businesses and so accord with Cox's (1999) value appropriation assertion. How often are those who realize the project on the construction site not told that it is a partnering project (because if they were told they would not act to maximize and pursue 'our contractual rights and opportunities')? Gruneberg and Hughes (2006) report that construction consortia are formed to win contracts – as marketing devices to give the impression of teamworking but, in reality, leaving much fragmentation – and, often, are little more than financial vehicles.

Ezulike *et al*. (1997) examine a variety of issues for constructors during the early years of PFI in UK. They report the commonality of constructors endeavouring to extricate themselves from PFI project arrangements following completion of construction to assist their moving on to further projects but retaining their traditional (financial) structure and ways of operating largely intact while building an experiential portfolio of PFI projects to aid marketing and securing further PFI work.

Propaganda, especially if viewed from a functional/intentions perspective, may occur in three main forms – positive communication, negative communication, and withholding communication; i.e. two active and one passive form. Positive communication exhibits bias of potential advantages – as much literature advocating partnering, PPP, PFI, etc., in construction. Negative communications are biased towards disadvantages/problems – as in discussions of constant use of contractors/subcontractors without competitive tendering. Withholding communication can relate to positive or negative issues – as in product suppliers failing to inform consumers of faults in the product and, thereby, encouraging the consumers to behave according to information known to be false (a failure of CSR also).

Professional practitioners in construction now operate largely under normal business competition and so, are subject to both the business performance requirements and those of professionalism (ethics). That is occurring at a time when there are pressures on businesses to be more diverse in responding to interests of their various stakeholders and to be more (widely) ethical in their behaviour (e.g. CSR; environmental impact reduction). However, such changes can be viewed as responses (also) to propaganda – by advocates of market competition, consumer groups and environmentalists – the objectives of some of which are more morally-determined than others. Propaganda is an ethical issue and, as such, has a moral and cultural foundation. Determination of what constitutes propaganda and any limits for acceptability are value-judgements.

Within the context of business process reengineering, Green (1998) notes the use of fear to generate attention and, then, to make recipients of the communications more susceptible to the contents – the changes sought by the perpetrators of the messages. Such fear is generated through assertions that deficient performance will ensue unless action is taken to follow the content of the messages; as such, much content of the messages can be left as implications through use of the prevailing socio-economic system and its performance imperatives as perceived by the audience (managers – as the organizational decision makers). Clearly, the endeavour is to persuade those decision makers to change the operating objectives and processes to yield greater (expected) benefits (value – see, e.g., Cox 1999) for the propagandists. Cox's (1999) perspective is reinforced by Hutton (1996) who notes the common performance imperative of companies to declare non-decreasing dividend streams due to the expressed criteria of fund managers – as the primary active investors on the global stock market. Clearly, the 'own value' (financial performance) criterion, and not CSR, is dominant.

CONCLUSIONS

The constructs of OCB and CSR are, *prima facie*, positive but the determination of their presence and extent is dependent on societal goals and norms. Their apparent presence may be occasioned through propaganda mechanisms, fear and other negative, even cheating, means. Pressures to perform apparent OCB (such as working extended hours) may be enhanced by the organizational climate or occasioned by rumour stories to engender fear of losing the job due to non compliance in order that the organization secures greater work output at zero (financial) cost, e.g. the construction industry in Hong Kong is known for its long working hours.

Construction is a technical medium of business activity. Its members are subject to self-interested pressures for outcomes from many diverse stakeholders. Stakeholder values, as performance requirements are expressed forcefully from individual perspectives. Thus, ethics, technical and business behaviours may conflict leading to distortions of apparent OCB and CSR behaviours. In many contexts, propaganda is rife in construction, often as a form of generic opportunism.

Whilst the 'goalposts' for extra-statutory CSR are advancing (environmental protection, health and safety, eco-labelling, etc.), often, apparent CSR actions are undertaken voluntarily to gain a foothold in a market or increase market share, to provide some immunity from potential liabilities (as in quality assurance and environmental protection certification) or as a taxation manoeuvre which also enhances the image of the organizations (e.g. charity donations).

If CSR behaviour, analogous to OCB, is regarded as behaviour in excess of norms and of legal requirements, then it comprises only ethical and discretionary categories relating to social issues. The philosophy of social responsiveness categories are less clear in their applicability for CSR as reaction and defence are usually in response to external forces – which may apply to accommodation also – leaving the only optional category to be proaction. (Even proactive measures may be taken in anticipation of future external forces – legislation etc.)

A COMPARATIVE STUDY OF GROUP INTERACTION

Christopher A. Gorse[1]

School of the Built Environment, Leeds Metropolitan University, Queen Square Court, The Northern Terrace, Civic Quarter, Leeds LS1 3HE, UK

Group interaction is a fundamental aspect of multidisciplinary construction projects, yet only a few studies of construction groups engaged in a 'bona fide' meeting exist. In an attempt to fill this gap, the Bales Interaction Process Analysis (IPA) method was used to observe and classify interaction from 36 management and design team meetings. By aggregating the data together a single profile of group interaction was produced. The profile represents the first attempt to model the communication behaviour of a management and design team meeting. Comparisons with existing IPA models show that there are similarities and differences between construction and non-construction related groups. Interaction features associated with task and socio-emotional behaviour are highlighted and discussed. In construction teams, the level of socio-emotional communication was much lower than the task-based interaction. Interestingly, while many suggest that construction is surrounded by adversarial behaviour, the level of conflict and disagreement found was lower than that found in many other contexts.

Keywords: communication, group work, meetings.

BACKGROUND

While teamwork and group interaction are fundamentally embedded in construction management few researchers have investigated this topic. Furthermore, although much is written on communication little of it is supported by research (Emmitt and Gorse 2003; Dainty *et al.* 2006). As a starting point, a detailed investigation into the communication behaviour of construction groups compared to other groups should help establish a contextual model of communication. Issues that are of specific concern and worthy of further investigation include aspects of interaction that relate to the management of relationships and tasks.

Selection of an appropriate research method

For nearly a century scholars have suggested that group communication can be viewed as task or emotionally oriented. Researchers today still recognize these two factors of group communication. And, although debated, the literature's prevailing ethos treats this distinction as an uneasy alliance, but accepts it as a key characteristic of groups (McLeod and Kettner-Polley 2004). These two dimensions are considered to be essential components in the management of interpersonal relationships and the accomplishment of tasks. For the group to exist and develop the members engage in relational communication (socio-emotional) and, to achieve outcomes, groups move through various phases of task-based discussion (Bales 1970).

[1] C.Gorse@leedsmet.ac.uk

Although there are a number of research methods used for recording group communication the Bales Interaction Process Analysis method provides a robust method with a clear focus on the socio-emotional and task-based components.

The Bales IPA method of observing, recording and investigating communication is well established. Having stood the tests of time it has been used in research methods that have produced seminal works such as Tuckman's (1965) model of group development and Belbin's (1981, 1993) work on team roles. Recent studies have used the method to investigate interaction in self-managed work teams (Armstrong and Priola 2001) and virtual environments (Chou 2002; Fahy 2006). Even with the advent of new technologies, different ways of working and new processes have not reduced the usefulness of this research method. Bales IPA is versatile and robust and although other methods claim to offer additional features, the longevity of use has resulted in a considerable body of information, which has steadily developed understanding of group interaction in various contexts.

The IPA observation method has seen a recent decline in use with researchers opting to use self-perceptions and interpersonal ratings from within the group. Two reasons for this shift is that direct observation is costly and time consuming and interpersonal ratings allows for all members to provide their perceptions of each other member, which yields rich information about biases and motivated perceptions (McLeod and Kettner-Polley 2004). What is lost with interpersonal ratings is the considerable detailed information and fine grain analysis of group behaviour and development that is only possible with direct observation (McLeod and Kettner-Polley 2004). Some research projects which have used interpersonal ratings to delve into members' beliefs have also supported their analysis with the Bales IPA direct observation. For example, Armstrong and Priola (2001), and Priola *et al.* (2004) made use of interpersonal ratings, the Bales IPA and discourse analysis to investigate cognitive styles and group work although their work is conducted in staged environments. Unfortunately where participants are requested to voluntarily take part in 'real world' research projects that require them to undertake additional tasks response rates to research demands suffer. It is commonly accepted that a low response rate (30–40%) to questionnaires is normal. Few researchers question what differences might be occurring between those who participated and those who did not. However, when attempting to model the interaction behaviour of a group it is necessary that all members of the group agree to participate.

Although direct observation is time consuming for the researcher, analyst and observer it places no resource implications on those being observed; indeed, it is desirable for those being observed to carry on as normal – not doing anything different. Interestingly the Bales SYMLOG system, which is based on interpersonal ratings, can take the participants three to four hours to understand and complete (Bales 1980). Emmitt and Gorse (2007) experienced considerable difficulties when attempting to obtain valid and consistent interpersonal ratings and reflections from professionals. Work demands and lack of interest meant that feedback sheets required from the professionals were given a low priority and the contributions and content varied with a significant number of professionals not responding with any meaningful content. Direct observation using the Bales IPA method, which places minimal demands on the participants, is an effective way of collecting interaction data from professional groups and is still as useful as it was in the 1950s when it was first introduced.

IPA and construction research

The Bales IPA has been used extensively in many fields, although rarely used in construction; exceptions include work by Gameson (1992), Gorse (2002, 2007), Bellamy *et al.* (2005) and Wallace (1987). However, Wallace used a bespoke methodology with components taken from the Bales IPA. Unfortunately the bespoke method, with many more categories than the IPA, unbalances the categorization process, meaning that even in the categories that are exactly the same, they may be apportioned differently from the IPA system. For example, where once an IPA category would have taken preference in coding a particular act, a communication category from another method may take preference. Thus, the original Bales communication description may receive reduced use because of the presence of another description. The Bales system can be used alongside other methods, but once mixed in a bespoke method the results produced are difficult to compare.

Examples of existing research that has used the IPA method to examine group interaction in other fields includes Bales' (1950, 1970) profiles of children, married couples and academic groups; Cline's (1994) study of disagreement and agreement; Landsberger's (1955) records of mediation meetings; Bell's (2001) observations of multidiscipline child protection teams and Fahy's (2006) comparison of face to face and online groups. Bellamy *et al.* (2005) conducted a study similar to that of Fahy's work, in construction, and looked at the difference between co-located and virtual design teams using the Bales IPA. Interaction studies from various contexts will provide data showing which environments produce similar interaction to construction. Where similarities are noted, the findings provided from the earlier research will also highlight issues that could impact on group interaction in construction projects.

RESEARCH METHOD

The data were collected from management and design team meetings. The meetings observed were collected from 10 different contracts with project values ranging from of 3 million to 8 million pounds sterling. A minimum of three meetings were observed for each case study. Observations were recorded using the Bales Interaction Analysis Process (IPA) technique, which identifies the communicator and the recipient (target of communication). The Bales method also permits classification of the statement into either one of six 'task-related categories' or six 'socio-emotional categories' (Table 1). The observer recorded the data using a prepared check-sheet with tick-boxes enabling the identification of the person speaking, recipient, and the interaction category that classified the statement used. The observer sat at the meeting table, and the participants were aware that the researcher was observing. The observer took no active role in the meeting. A brief qualitative note was made of the issue being discussed.

Table 1: Bales 12 interaction categories (adapted from Bales 1950: 9)

ID	Bales' categories and description	Group
1	Shows solidarity – show support, raises others' status, gives help, encourages others, reinforces (rewards) contribution, greets others in a friendly manner, uses positive social gesture, shows element of kindness.	Social-emotional area Positive reactions. Behaviours and gestures used to engage others in positive manner, can be used to encourage commitment, help build and strengthen relationships.
2	Shows tension release – jokes (supportively), laughs, shows satisfaction, relieves or attempts to remove tension, offers way out of problem, expresses enthusiasm, enjoyment, satisfaction.	

3	Agrees – shows passive acceptance, acknowledges others, shows understanding, complies, cooperates with others, expresses interest and comprehension.	
4	Gives suggestion – makes suggestion, provides direction or resolution, implying autonomy for others, attempts to control direction or decision. Makes clear and firm statement. Shows the way forward.	Task area: neutral Input and attempted answers. Acts used to give, exchange and develop information, understanding and control. Provides information and clues about context, topic, goal and direction.
5	Gives opinion – offers opinion, evaluation, analysis, express a feeling or wish. Seeks to analyses, explore, evaluate or enquire. Provides insight and reasoning. Offers view, without imposing direction on others.	
6	Gives orientation – provides background, further information, repeats, clarifies or confirms. Brings relevant matters of fact into the forum, acts that assist group focus on the context rather than the direction.	
7	Asks for orientation – asks for further information, repetition or confirmation. Draws out issues, facts and background information. Acts used to request relevant information and understand the topic and context.	Task area: neutral Questions and requests. Information finding and question asking. Acts used to request, seek, draw, search, withdraw, analyse and explore information. Also includes requests for direction
8	Asks for opinion – asks others for their opinion, evaluation, analysis or view. Requests that others express how they feel or state their preferences. Acts used to request and explore reasoning.	
9	Asks for suggestion – asks for suggestion, direction, possible ways of action. Requests for firm contribution, solution or closure to problem. Asks another member to take on autonomy of others.	
10	Disagrees – shows disagreement (without any anger or tension), passive rejection, expresses position to withhold help, does not support view or opinion, openly fails to concur with view, rejects a point or suggestion.	Social-emotional area Negative reactions. Include non-conformative acts that show little emotion to outward aggression. Behaviours used to disagree, reject information, question commitment and threaten relationships.
11	Shows tension – shows concern, apprehension, dissatisfaction or frustration. Persons interacting are tense, on edge. Disagreement supported by negative emotion. Acts that express sarcasm or are condemning.	
12	Shows antagonism – acts used to deflates others' status, asserts self on others. Openly suppresses another member, purposely blocks another or makes a verbal attack, expressions of aggression and anger.	

RESULTS

The line graph (Figure 1) representing the management and design team meetings illustrates the trend of group interaction found in the management and design team meetings. This provides an example of the group interaction norms operating within the meeting. The results show that the groups use a high amount of task-based interaction (categories 4–9) and a relatively low level of socio-emotional communication. Socio-emotional interaction represents the interaction used to build, develop and maintain relationships and that used to engage in conflict and threaten relationships. Socio-emotional interaction is often termed relationship communication, the acts help to engage, strengthen, threaten and withdraw from relationships.

Examining the results in more detail: the groups' use of giving task-based interaction (categories 4–6) is consistently higher than that of requesting task-based interaction (categories 7–9). The positive socio-emotional interaction (categories 1–3) is also consistently higher than the negative socio-emotional communication (categories 10–12). The level of positive and negative emotional interaction is low. Although the construction sector is often described as an emotional and volatile environment, this is not evident from the data. Although it cannot be said that this model is representative of all construction site meetings, it was drawn from a sample of 36 meetings from which 15 077 communication acts were observed. On this basis, the model shown provides the most comprehensive picture of group communication during construction meetings to date.

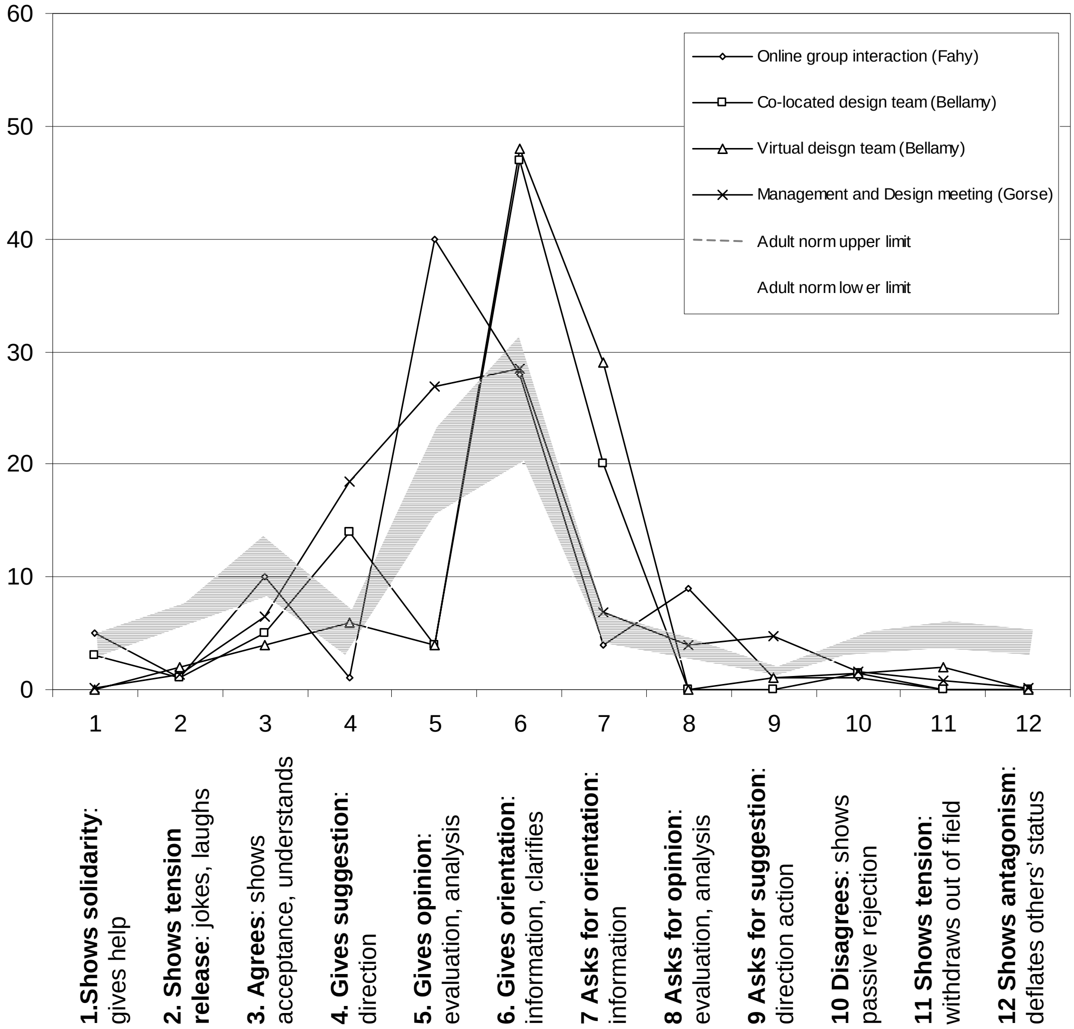

Figure 1: Graph showing Bales original study of Adult norms and studies of construction based interaction

DISCUSSION

When comparing the line graph (Figure 1) to previous studies the results shows considerable difference between the construction-based studies and the upper and lower limits of interaction norms as depicted by Bales (1970). The shaded area of the graph represents Bales' normal ranges of interaction. All of the construction-based studies show very low use of the socio-emotional acts, especially when compared to Bales normal range. Fahy's (2006) study, which is based on students' online interaction, is the only graph that drifts into Bales normal zone. Results from previous studies that have investigated construction professionals' interaction, such as Wallace (1987) and Gameson (1992), have also found low levels of emotional expression. Much of Bales' work that was used to produce the normal range was based on student, counselling and social groups. The few studies that have investigated work groups show much lower uses of socio-emotional communication than that found in other contexts (Wallace 1987; Gameson 1992; Bell 2001; Bellamy *et al.* 2005). Studies by Bales (1970) found that groups which used a low amount of socio-emotional interaction were often in the early stages of group development.

As groups develop and become more familiar with each other their behaviour changes. Individuals within the group initially use task-based communication, tentatively gathering information on the other group members' personal behaviours, beliefs and attitudes before using socio-emotional interaction. Before openly engaging and committing into a relationship group members need to understand other members' motives and how they react to different messages. As each member engages in interaction and discussions continue a social interaction structure develops (Bales 1970).

Socio-emotional interaction supports the development of interpersonal relationships. By agreeing and disagreeing with issues interpersonal bonds and commitments can be strengthened and reduced. As the socio-emotional structure develops members become familiar with other members' communication behaviour and the level of socio-emotional interaction increases. Groups that reach the later stages of group development show an increased use of socio-emotional communication (Heinicke and Bales 1953; Bales 1970). Developed groups are said to have established their behaviour norms with individual members being more confident to express socio-emotional acts in order to manage relationships and work through the group tasks.

Group communication using Bales IPA

There are certain characteristics that are said to be associated with specific types of groups. For example, the behaviour juveniles have been found to be unstructured, lacking control and characterized by outbursts of emotion. Groups of children offer an example of what has been described as uninhibited and uncontrolled behaviour (Bales 1970; Socha and Socha 1994). As people mature their behaviour becomes more restrained (Socha and Socha 1994). Clearly the behaviour of the work groups, including that of the management and design meetings, is not emotionally expressive. Indeed much of the discussion is task-based as members attempt to express, understand and solve problems. In adult groups, information and suggestions are often supported by explanation; generally, communication in adult groups is structured, controlled and restrained (Bales 1950; 1970). Adults do not normally express high levels of extreme emotional behaviour. While the behaviour of construction professionals may be different from that of other groups, and not within the Bales normal range for adult groups, it does not resemble the behaviour of juveniles.

The few studies that have looked at work groups (Landsberger 1955; Gameson 1992; Bell 2001) provide initial evidence that the working and commercial environment reduces emotional communication to a lower level compared with other studies. Studies of online communication have found very low levels of socio-emotional communication (Bellamy *et al.* 2005) and Fahy (2006) noted a complete absence of negative socio-emotional interaction during computer-mediated discussion. However, these initial results should be treated with care. Criminal reports and general news shows that emails, text messages, blogs, photographs and identity impersonations can be emotionally manipulative (Channel 4 2006). Digital communication and emotional content is an area that requires further research. Clearly, the communication medium and environment has an effect on the nature and impact of communication.

The management and design team meetings shown in Figure 1 and the other work-based studies indicate that task-based communication consumes most of the meetings' time. Although many of the work-based issues discussed in the meetings necessitate the exchange of ideas, information and questions, and, to explore issues in depth, the use of questions and requests for suggestions are needed, the socio-emotional interaction plays an important part in the process. At its most basic level socio-emotional interaction includes agreeing and disagreeing; such acts are obviously essential in the discussion of problems. Socio-emotional acts include negative emotional statements and acts that are antagonistic or even aggressive; these acts can be used to weaken and threaten the relationship. However, all negative socio-emotional acts, including basic criticism and disagreeing can threaten the strength of a relationship. Positive socio-emotional acts such as agreeing, showing support and being friendly help to build and stabilize relationships (Bales 1970). In order to successfully discuss problems group members need the skills to enquire, analyse, disagree and show support. If issues are not discussed properly and people do not have the skills to show concern and disagree then problems could develop in the future. If a balance between positive and negative socio-emotional exchanges is not maintained the project relationships could be threatened.

In the meetings observed the exchange of socio-emotional interaction, although responsible for only a small proportion of the total interaction, resulted in a notable change in the group dynamic. Where negative emotional exchanges occurred the group became very attentive and focused. If arguments emerged some members appeared anxious. When positive emotion was used the mood of the meeting became more upbeat and relaxed. Even though socio-emotional interaction in construction groups is minimal it has an important role to play in the management of discussions. Further research is necessary to uncover how socio-emotional interaction is being used. By comparison with other studies it should be possible to establish an understanding of the effects of various communication acts. Knowing how we use communication and what effects the messages used have on others should be a basic part of the construction managers' training, yet such information is not widely available.

CONCLUSION

This study provides an overview of group interaction within management and design team meetings on construction sites. The results show an interaction pattern that has greater association with other work-based environments than it does with earlier studies of social situations. Earlier studies of interaction norms are different from those found in the more recent studies of work groups; a new set of interaction norms for *bona fide* work groups should be established. Further investigation is also required into the area of socio-emotional interaction and its link with project relationships. The use of negative and positive socio-emotional interaction within the site meetings was low. While this is inconsistent with reports that suggest that adversarial behaviour in the construction industry is endemic, failure to engage in socio-emotional interaction and resolve problems as they occur could lead to latent tension that threatens relationships. Socio-emotional interaction is directly tied to the resolution of task-based problems that require multiple parties. Parties must manage the relationship and tasks. Problems should be properly and rigorously discussed. Such discussions will result in stress that needs to be managed so that relationships are sustained. Clearly, such issues are fundamental to the construction industry and further research is necessary.

DEFECTIVE WORKMANSHIP – ALIVE AND WELL

Wilson Barnes[1]

School of ACC, Southern Polytechnnic State University, 1100 South Marietta Parkway, Marietta Georgie 30060, USA

This paper draws from a larger study that investigates defective workmanship through an interpretive approach generated by methodical analysis of construction cases drawn from English jurisprudence. That process serves to highlight the primary causal factors as well as secondary (sometimes proximate) causes of defective workmanship, and enables identification of repetitive characteristics or indices. Through ordered aggregation of these characteristics from readily available case histories, relationships are identified leading to a fuller understanding of the cause–effect linkage and of the dire consequences frequently realized. While the broader study included a similar analysis of data and interpretation for appropriate construction cases from American jurisprudence in the state of Florida, this paper discusses the resultant identification of architectonic location, conduct causal factors, and legal theory involved in the jurisdiction of England/Wales. Conduct causal factor identification was considered fundamental to classification of defective workmanship causes and its genesis is discussed more fully herein to facilitate understanding of the overall study structure. Derived knowledge of the resultant statistically grounded conduct causal factors will hopefully lead to better contractor performance and profit. The basic study examined cases reported from 1970 to 1996. This paper will present that information with frequent references to the identified data of interest and a brief discussion of updates to 2005. Despite a varying prevalence of legal favoured interest over the years, defective workmanship remains a persistent underlying reason for dissatisfaction of the construction product customer.

Keywords: building defects, construction law, culture, defective workmanship.

BACKGROUND

The construction processes with respective provisions and players come together in a complex coordinated manner. That orchestration is filled with ample opportunity for omission, discontinuity, conflict and dispute.

It can be argued that the construction delivery system is a network of interacting forces that define process. Two of the most important forces in the process are the contract, with its many variant conventions and regulatory control, with its numerous levels of coverage and enforcement. The contract and regulatory control (control by the public regulator) are fundamental to establishment and pursuit of relationships, responsibilities, duties and rewards. These forces, crucial to the operational climate, are ripe with potential for misinterpretation, bad performance, misfeasance and abuse.

As with any process, no matter how rigid or loose-knitted it may be defined, that of construction is subject to exploitation by those who seek out holes in the net or slack

[1] wbarnes@spsu.edu

in the system. This was discussed extensively by Clegg, especially with regard to the potentials mentioned above (1992: 128–44). Cheetham noted, ‘It is the complexity of contractual obligations and the large number of co-operating organizations that has given rise to an extremely litigious industry’ (1993: 86–98). Despite a generally high order of professionalism among practitioners and manifest professions of goodwill, there are those whose conduct is driven by opportunism and the easy way out. Although most people want to avoid legal entanglement, ‘the nature of the construction process seems inevitably to lead parties frequently to the brink of legal action and often beyond’ (Uff 1996: 1).

Lack of client (owner) satisfaction with our built products is deeply troubling as well as being a major source of disputes and extra costs. Similarly, weak coordination within our industry, poor performance on the job site, and defects in the final product all contribute to poor public image and mistrust. While poor performance on the job site is not a mono-dimensional problem, it is a major underlying feature of flawed process that leads to unsatisfactory buildings and to customer dissatisfaction. One clearly identifiable aspect of poor performance is defective workmanship. This aspect is potentially remediable. To prescribe a remedy it is necessary to understand the cause.

INTRODUCTION

This paper is a compact partial summary of an extensive study to investigate causal factors of conduct underlying defective workmanship in construction as documented in the public sector in England/Wales (Barnes 2000). To exert a modicum of control, England and Wales operate under what can be called a conventional regulatory system having a subtle and loosely enforced impact outside the courts on how work is done.

METHODS

The basic investigation relied primarily on data from cases appearing in published law reports and public record transcripts of unreported cases. The category of such cases represents a small fraction of all cases brought into court (Carter 1996), since most disputants hopefully appreciate the probable value of early settlement. The collected data were limited by selection of those cases for reporting, the inconsistent focus of the reporting sources and by the variable conduct of the regulatory process. Unreported cases from 1990 to 1996 which were available in the Royal Courts of Justice Library, were also reviewed and appropriate transcripts chosen for the study.

The primary time frame of the base investigation is the 26-year period leading up to and through 1996. This period was been selected because of both the relevance of law and the availability of reference material in the jurisdiction of interest. While reference may be made to matters of influence prior to that time, the basic issues will be pertinent to that defined period. The data are drawn from an advancing frame of temporal and legal reference. While normalization of certain independent variables was assumed, the impacts of the conventional regulatory system of England and Wales are presumed to have been in force as prescribed by law. The distinction between conventional and unconventional systems is set by Blachere (1993) in discussing enforcement of building laws and regulations.

Eight human-based causal factors of defective workmanship were identified and assigned to identifiable features of the examined cases. These causal factors or characteristics define the sphere of cause considered in the study. See Table 1.

Eight architectonic sub-categories were established to bin the construction features of buildings/structures represented in the various profiled cases. These sub-categories define the sphere of construction activity considered in the study. See Table 1.

Eight categories were also defined for the legal doctrine or theory associated with each of the profiled cases, organized to permit multiple characterization where it is appropriate for conditions of the individual cases that have been profiled. See Table 1.

Construction disputes often lead to litigation that in turn fails to address the real source of manifested problems. These problems are often associated with technically unsatisfactory work products that are directly related to defective workmanship. While the underlying causal factors are sometimes identified and appropriate remedies prescribed, this is a remedy to compensate for the wrong, and the outcomes, though accessible to the public, are rarely made known in a constructive feedback manner.

A literature review focused on studies that address features of the construction process and completed product from the aspects of what kinds of things went wrong and what kinds of parties were responsible in what way. This was basically a review of relevant studies and condensed descriptions of influential writings that was an informative and productive concentration leading to structuring of a research methodology. Genesis of the causal classification system for the study was derived from this material.

The relevant law was described as not addressing defective workmanship in a specific manner but incorporated under numerous better defined legal theories and defended against by embodiment of broad performance requirement type language in statutes and contracts. The major strands of law affecting defective workmanship are tort, contract and statutory. The complex nature of tort law, especially negligence, as applicable to construction was discussed advancing to the then current state of English law as defined by the House of Lords in 1990 in *Murphy* v. *Brentwood Council* [1991] 1 AC 398.

The study employed a mixed quantitative and qualitative approach. The research was open-ended favouring grounded theory and analytical induction. Behavioural culture in construction was validated as an area that lacks significant exploration and resultant theory. The research considered settings and people holistically and sought a larger understanding from patterns in the associated data. A comprehensive presentation of numbers was suggested as having value in defining causal modes of significance.

The characterization and profiling of data from selected law cases led to structuring of an attribute table that in turn facilitated the search for themes and relationships. Thus the development from phenomena of an individual case to the structured presentation of many for analysis was realized. A common case report form eased compilation.

The choice of legal cases as the primary source of defective workmanship evidence is based on several facts. First, it is well known that although many contractors readily acknowledge the existence of the malady, few will willingly admit to or detail their own culpability in this area. Second, legal transcripts in whole or reported in part are an unimpeachable source of verity with regard to contractor performance. Third, the statements of judges in many cases speak directly to defective workmanship and its underlying causes, frequently coinciding with the study classification factors. And fourth, previous research and publication in this area by the study investigator found good reason to choose law cases as a major primary source of data for the study.

The phrase ‘work that is not done right’ begs the question of what is right. On the one hand we must deal with that which is legally right; or, if guided in a rule-bound manner to what is not wrong we can say that we have satisfied the letter of the law. The concept of right is a feature of culture and in our increasingly multicultural, ethically diverse and self-oriented society it is a concept of considerable fluidity and softness. What is all right for one is not so for another. In the complex philosophy of law and morality, Raz notes that our modern societies are characterized by moral pluralism that compounds the difficulties of predictable choice. In discussing various law and morality issues he also notes that the common law is regarded by the English middle classes as part of the English genius; but, '… working-class English people have traditionally felt that the law is not theirs but that of the upper classes'; and this is often manifested in a disregard for the law (Raz 1995: 310).

The subject of defective workmanship is recognized in many studies addressing the adjacent issues of defects, quality, cause and control, disputes, claims, and other matters associated with execution of the work. Notable among these are a handful by individuals who probed more deeply into the reasons behind the manifestations. They individually addressed different aspects of the defective work phenomenon and identified causal characteristics that have a remarkable unity. That unity led to factor selection. Those individuals or organizations are listed hereafter with major specific characteristics that they focused on or identified through broad surveys and research. The causal factor identity underpins the entire study and is discussed more fully here.

Porteus is exceptional among that above-mentioned handful in his focus on human error in the processes of construction. Porteus (1992) noted that his work, 'penetrated beyond the general terms "human error" and "negligence" to expose some details about the sorts of mistakes people make when designing and constructing buildings'.

Much was learned from selected writings on quality. Cheetham and Carter addressing the site execution of works note that many reports show workmanship as blameworthy as design and material specifications for failure. David Seymour in his many writings, notably in *Construction Management and Economics*, has provided abundant material. Low, who studied with Seymour, developed a keen understanding of the culture and incidence of defective workmanship (Low 1987). He gathered fact and opinion at many levels including assertions by the workers that they know what is to be done.

Features of interest to the base study that recurred in the primary literature have been listed below. Selected features and their author sources are listed. These were then distilled into a trial classification of conduct factors and a theory structure to promote orderly collection and reduction of data while testing selection of the factors.

1. Clegg (1992) – cultural environmental influence on site personnel (indexicality); poor communication; weak management/supervision.
2. Barnes and Mitrani (1994) – avoidance of financial responsibility by clients and first tier; improper job site procedure; poorly conducted management, weak management/supervision; use of court records as information source; lack of knowledge; poor communication; poor workmanship; contract not understood; overemphasis on first cost (greed).
3. Watts and Scrivener (1993) – use of court records as information source; sources of dispute: site and execution of the work; quality; payment; negligence; damage claims.
4. Porteus (1992) – natural causes vs. human nature; human error, sometimes called negligence; poor communication; dereliction or negligence; ignorance or lack of knowledge; overemphasis on first cost.

5. Burati and Farrington (1992) – erroneous methods or procedures; omission of activity or task.
6. Thornton (1986) lack of knowledge; blunders, errors and omissions; overemphasis on bottom line; lack of supervision; poor communication.
7. Knocke and CIBW87 (1993) – unforeseeable human action; errors and omissions.
8. Cheetham and Carter (1993) – lack of good practice compliance; weak coordination (communication).
9. Page/Murray (1996) – poor supervision; faulty workmanship; widespread ignorance; negligence; and cost-cutting practices.
10. BRE Report (1990) – inadequate skill and knowledge; importance (lack) of site supervisor experience.

Applying the features specified or probable/possible in the numbered sources to a trial list of factors assumed from the literature and contextual research, the base study found a nominal distribution that gives verification to the selection of at least four of the factors. Bold type indicates direct reference to that feature in the represented source, normal type indicates a probable or possible reference or implication.

Causal factors	*Source*
Comprehension of scope	**2**
Lack of knowledge	**2**, **4**, **5**, **6**, 7, 8, **9**, **10**
Excessive haste	**2**
Simple greed (incl. overemphasis on first cost)	**2**, **4**, **6**, 7, **9**

Despite its pervasive nature in underlying many unsatisfactory features of buildings and other structures that eventually become subject to dispute, the fault of defective workmanship does not have its own designated niche in the law. True, it is implied in defective products, and it is referred to generously in the common law. It is even written into statute such as requirements within the Defective Premises Act 1972 (applying to dwellings only and infrequently invoked), and the Building Act 1984 which authorizes building regulations that may prescribe the manner in which work is carried out (see Building Act 1984, Schedule 1). The Building Regulations 1991 as amended and incorporating regulation 7 dealing generally with workmanship, and the application of BS 8000: *Workmanship on building sites*, Parts 1-1, flow from that latter authority. In spite of such emphasis and its frequent relevance to litigation, defective workmanship *per se* is not recognized as a separate tort. A tide of tort actions however, usually based on negligence, has ebbed and flowed over the years as guided by decisions of the courts.

Given the lack of a specific niche in the law for defective workmanship, it can also be found that as a specific subject, defective workmanship has not been widely discussed or researched by academia or the legal community. There are the excellent studies focused on the technical nature of defects as commissioned by government; and, exceptionally, Duncan Wallace, in *Hudson's* devotes much attention to defective work (Duncan Wallace 1995).

Contract is one major strand of law under which obligations arise for defective workmanship. It also imposes statutory obligations such as compliance with the building regulations. The terms of contract law are relatively easy to understand. If you agree to certain terms, you are obliged to satisfy them. Failure to do so entitles other parties to the agreement a favourable position for negotiation or legal remedy.

Tort, as the second major strand of law threatening defective workmanship, is less easy to understand. John Uff notes, 'Tort can be defined as a civil wrong independent of contract; …' (1996: 415). Simple! But in spite of the independent nature, the law of tort is still part of the control framework for getting a project done. That is an easy way for the contractor to think of it; as an essential code or set of conduct guidelines.

In talking about research in the construction industry, Fellows (1997) notes that, 'very little research has been done to determine the culture of the industry – the values and beliefs which govern people's behaviours'. Values, beliefs and shorter term stimuli such as leadership or lack thereof can determine immediate behaviour. Bad workmanship is a manifestation of behaviour in specific settings.

It was determined that a multidimensional array was necessary to characterize the various cases under study. Three organizational fields of indices were identified as appropriate measures of defective workmanship with each given eight sub-categories to assist in classification of cases through notation of incidence occurrence.

Table 1

Architectonic*	**Causal**	**Legal**
Soils, foundations	Scope comprehension	Fraud
Substructure	Lack of knowledge	Misrepresentation
Superstructure	Excessive haste	Breach of contract
Envelope/cladding	Simple greed	Negligence
Roofing	Poor communication	Nuisance
Services	Weak estimate	Statutory breach
Finishes/specialties	Weak supervision	Warranty breach
Temporary structures	Temporary structures	Trespass

*A term used here to indicate architectural or construction location.

In discussing theories of ill-defined behaviour, Cohen (1995) noted, 'We can often recognize phenomena long before we can define them, and many important phenomena have been studied for years without benefit of a consensual opinion.'

Neil Pepperell (1991) noted that much of our inability to stem the flow of defective work is tied to our failure to articulate clear definitions of quality. Although much of the work he describes parallels the BRE concentration on technical aspects of defects, Pepperell does acknowledge that a significant grey area exists in designation of responsibility for defining technical standards, and moreover, in organizing the supervision of their implementation.

That latter weakness is discussed frequently by I.N. Duncan Wallace in his many writings. It is puzzling that an issue championed by such an authority as needing attention has received so little. In one of his more colourful articles Duncan Wallace takes sharp aim at current practices that have encouraged rather than discouraged defective work. Namely, he cites four lines of thought or proposition that include: passive contractor attitudes that are buttressed by industry-commissioned reports identifying design deficiencies as the major factors; consistently ineffective contractual remedies; failure of governmental authorities to establish the proper measure of control and regulatory enforcement; and lastly, attempts to finesse the root causes of defective work by insuring against it and passing the cost on to the consumer. He rightly dismisses this latter proposal as another red herring to draw attention away from the contractors' failures and blames a 'producer-oriented government' for not taking firmer control. He is one of the few who have recognized the pernicious effect of indifferent and evasive contractor attitudes concerning supervision of the work. Further, he has identified potentially corrective action; e.g., 'surely the function of contractor supervision, whether by contract or site managers or agents, or by general foremen, is in a modern society far too important a task to be left to individuals who are not necessarily either licensed or qualified' (Duncan Wallace 1990).

Duncan Wallace (1986) does not dance around the issue of responsibility by positing the architect, supplier, local authority or central government as culprit. He lays much of the blame directly on the contractor and subcontractor, who historically have worked successfully to shift the balance of blame for defective work away from themselves and on to the other parties.

The stage was set for analysis of defective work undertaken in the base study by a case clearing the House of Lords in October 1965. In *East Ham Corporation* v. *Bernard Sunley and Sons* a successful appeal of the Court of Appeal reversal returned a breach of contract judgment for defective work. The presiding judge in appeal noted widespread faults in stone panel fixings that ultimately required re-fixing or replacement. (*East Ham Corporation* v. *Bernard Sunley and Sons* [1966] AC 406; [1965] 3 WLR 1096; 3 All ER 619; 2 Lloyd's Rep. 425, HL; reversing [1965] 1 WLR 30.)

In the first decade of the study time frame, selected residential cases out-numbered those of a commercial or industrial nature almost two to one. Defective foundations and/or soils dominated the architectonic characteristics of the early decade cases.

The second decade brought a reversal of the building type reflecting dominance of defective workmanship with commercial and industrial appearing two to one versus residential in the selected cases.

In the mid decade from 1980 to 1989, just three of 29 selected and charted cases sounded in contract only. The other 26 were characterized by tort alone or tort and contract jointly.

The final decade (albeit a partial one) of this study time frame is from 1990 to 1996. This period encompassed the end of the *Anns* doctrine and saw, after *Murphy*, a dominance of contract over tort as the legal theory of choice and success. (*Anns* v. *Merton LBC*; *sub nom*. *Anns* v. *Walcroft Property Co Ltd* [1978] AC 728; [1977] 2 W.L.R. 1024, HL.)

The decision of the House of Lords in *Murphy*, a defective design case, brought about a realignment of thought in the legal community. As mentioned previously, lawyers began to focus on framing causes of action related to contractual or statutory obligations. The time limitations for these actions became more meaningful as the alternative opportunities for successful litigation were greatly diminished (*Murphy* v. *Brentwood Council* [1991] 1 AC 398).

FINDINGS

The findings resulted in numbers that have been aggregated in summary matrix tables. Those summary aggregations were used in contingency tables to interact and generate further numbers exhibiting high count intersections of defective workmanship causal conduct modes. The high value intersections represent areas of consideration for preventive measures and enhanced performance. All intersections are represented in causal conduct vectors across the variables of architectonic location and legal theory. All of the cases representing numbers in the matrix tables were analysed thoroughly and a brief prepared citing numerous classification features such as the judge, court, date of incident, job venue, contract amount, construction period and contract type. Issues and outcomes were discussed with relevant quotations from witnesses, counsel, principals and the judges. Owing to space limitation, only an end summary appears here.

Table 3

Causal f (Architectonic)	England/Wales		**Causal f (Legal)**	England/Wales
Weak supervision	81 / 36.5%		Weak supervision	80 / 37.6%
Lack of knowledge	57 / 25.7%		Lack of knowledge	61 / 28.6%
Poor communication	47 / 21.2%		Poor communication	39 / 18.3%
Simple greed	21 / 9.5%		Simple greed	22 / 10.3%

It is easy to conclude that these four causal characteristics listed above represent conduct problem areas for construction project managers and companies.

Moving forward in time from the base study, important incidents occurred beginning in 1996 which altered the complexion of legal treatment that defective work issues would be subject to. The Housing Grants, Construction and Regeneration Act was passed and affected construction contracts after 1 May 1998. Section 108 of that Act established adjudication and gave parties a right to refer disputes to a mandatory procedure defined in the Act. On 9 October 1998 the Official Referees were replaced by judges of the Technology and Construction Court. On 26 April 1999 the Rules of the Supreme Court and County Court Rules were replaced by the Civil Procedure Rules. The CPR have been updated constantly since that time with the latest revisions of the Pre-Action Protocol for Construction and Engineering Dispute and the Pre-Action Protocol for Housing Disrepair Cases. In general, these latter encourage early cooperation between the parties in the interest of early settlement without or with minimal litigation. Revised rules on costs, claims and counterclaims are also of interest and they along with the protocols all impact on defective workmanship issues that might rise to the level of litigated cases (Anon 2006). Also, there has been a further strengthening of case law stressing the understanding of relevant contractual language as a reasonable person would versus literal interpretation of unclear words as cited in *Keating* (Anon 2006: 3-023). Whatever the underlying reason or reasons may be, there seem to be fewer law reports dealing substantively with defective workmanship.

A preliminary review of the law reports since 1998 reveals numerous cases of pertinence to this study, major and minor in nature, that reflect defective workmanship. With the three from the base study not included in its tabled results, they together indicate continuation of the earlier pattern highlighting causes of supervision, knowledge and communication. Those further cases reflecting significant defective workmanship include the following at a minimum: *Department of National Heritage* v. *Steensen Varming Mulcahy, Balfour Beatty Ltd, Laing Management Ltd* [1998] EWHC Technology 305; *Baxall Securities Limited* v. *Sheard Walshaw Partnership* [2002] EWCA Civ 09; and *Catlin Estates Limited* v. *Carter Jonas* [2005] EWHC 2315 (TCC). A detailed study of this more recent period will be presented in the future.

CONCLUSIONS

Since at least the time when the Code of Hammurabi prescribed one-for-one comparable restitution or penalty for defaulting contractors, humankind has struggled with discouraging and preventing defect-associated faults, and controlling contractor performance. The institution of strong mechanisms and a culture of professionalism is needed to establish and foster control of contractor performance. To the credit of the industry, such measures have been initiated on many fronts. The rub arises in human nature. The simple act of working for hire inspires some to do their best, strive for excellence, and achieve a high level of performance. Some do this of their own accord, others respond to leadership. Others need urging or goals or requirements.

The dark side of reality is that there are those who are seldom motivated to do their best, even if they know what they should do. They are often working for wages and the profit motive does not reach them; or, they are focused on short-term gain. Thus, in respect of work not being done properly, we must acknowledge that there are many within the workforce that lack either the motivation to do well, or the knowledge of how to do it, or both. The need to accommodate this phenomenon arises constantly in an industry that in recent times has been ill equipped to handle it, and is under constant pressure to produce work in a timely and cost competitive manner.

Finally, there is the greed for money above all else, and the tragic end often arrived at by the contractor with an unbridled profit motive shaving quality or hiding bad work in an attempt to get done with the least effort and cost. Understandably, the subject of bad workmanship is not one that contractors will talk about readily. They are especially loath to do so when the discussion involves their own operations or labour forces.

As do other arenas of endeavour in life, the construction industry attracts both the best and the worst of human qualities. Ingrained cultural attitudes are difficult to change. There has been much discussion of contractor licensing or accreditation in the British construction industry. Such a mechanism could be very beneficial if it were devised to address all levels of activity, and if it were enforced to protect the general public whether they be homeowners, corporations or a government department.

Access to the records of dispute resolutions out of court is privileged and not available to this study. Despite that, and although the costs of resolution are better controlled and the impact on the courts seems to have been lessened through adjudication, the evidence in law reports remains and defective workmanship is still very much alive.

BOOK REVIEWS IN CME: A CRITICAL PERSPECTIVE

David Langford[1] and Mike Murray [2]

1 School of the Built and natural Environment, Glasgow Caledonian University, Cowvcaddens Road, G4 OBA, UK
2 Department of Civil Engineering, University of Strathclyde, 107 Rottenrow, Glasgow, G4 ONG, UK

This paper analysis the book reviews appearing in five volumes of *Construction Management and Economics* (Vols 20–24). This provided a sample of 52 reviews. It analyses each review in two ways: firstly, by the factual information about the published book. These include the subject area of the books published, who publishes them, the balance between edited and written books, the price range and pence per published page by each publisher. The second part of the analysis relies upon an interpretive framework. Each review is assessed for its qualities of being informative about the content, purpose and audience for the book under review. Additionally the review will be evaluated by reference to its critical facility and whether the review offers an uncritical perspective or offers a more engaged opinion. Finally, the reviews are assayed by whether its reviewer recommends the book to its stated or perceived audience.

Keywords: Book reviews.

INTRODUCTION

Books are a major resource that sustains an academic discipline. They provide a framework of scholarship from which students and other aspiring professionals learn their trade. They also provide a valuable accessible shortcut to the wealth of research that underpins an academic discipline. Books provide the instruments for sifting and evaluating research. In all, books are important. Consequently, the evaluation of books published will be a critical academic task in support of a discipline. This paper evaluates 52 book reviews appearing in *Construction Management and Economics* (*CME*) over the period 2002–2006. It undertakes a quantitative review of who publishes, what is being published, how much each publisher charges per page of published work, the trends in the books being published in terms of specialism and forms of production. The second part evaluates each review on three subjective criteria: how informative are reviews, how supportive are reviewers and whether the reviewer recommends a book to readers. The piece is notable for the absence of references to other work.

There is little literature available on how to review books and an extensive literature search only revealed works by Orwell (1968) who commented upon the nature of book reviews. He notes that Chesterton (1968) identified a distinctive category of book, which he called a good, bad book. These are books with no literary pretensions, but are extremely readable books and so found a place because of the sheer natural grace, erudition or intellectual power evinced by the writing, Orwell comments that there are no literary tests to show where superiority lies. The formation of an opinion should involve academic ascetic judgement and a view of whether the book is worth buying. Orwell celebrates the prose of music hall and playfully says that musical songs are better than many of the poems appearing in formal anthologies. He cites:

> Come where the booze is cheaper,
> Come where the pots hold more,
> Come where the boss is a bit of a sport,
> Come to the pub next door!

A more sombre Orwell (1968) writes in an essay entitled "Confessions of a book reviewer" where he presents reviewing as a less than joyous task especially when confronted with reading about which he knows little and earns less. He wants to write a review saying that a book is worthless and that "the great majority of reviews give an inadequate or misleading account of the book". Orwell's ennui with reviewing leads him to conclude that specialist reviewers are required for specialist books and invariably this is the practice in CME book reviews.

In a further exploration of reviews, Orwell (1968) undertakes a meta-review of Penguin books as a distinctive category of publishing. He comments upon the personal economics of book buying and this will be considered further when publishers are compared in respect of price per page of published work.

More recently, an essay appeared in the *Spectator* by Max Hastings (2006), the military historian who compares the practice of book reviews with that of critics of theatre and other performance arts. He argues that book reviewers are much gentler than the critics of performance arts. He speculates that the reason for this is that the film critic has no aspirations to be a film director or a movie actor; similarly, the theatre critic does not seek to be a playwright. However, the book reviewer is likely to be drawn from a small circle of known writers with literary editors commissioning known authors to review books to appear in the review section of the daily or Sunday newspapers. Hastings sees this as a complicit circle; authors are reviewers and reviewers are authors. Consequently, reviews are gentle since all know that the boot is going to be on the other foot at some stage in someone's career. The literary world is notable for falling out after bad reviews have been published, perhaps the most notable being between V S Naipaul and Paul Theroux after Theroux had savaged one of Naipaul's books.

Recognizing the pitfalls of reviewers and critics being drawn from a closed circle, Young (2007) argues that the critic needs some distance from expertise in the subject under review in order to offer a populist rather than expert opinion on what is being reviewed.

This antagonism between author and critic is explored by Smith (2007a 2007b), who takes to task book reviewers she believes to be too cynical. She calls for non-cynical criticism that reveals the personal tastes of the reviewer. Her view is that for books to be well received by reviewers they have to confirm to a "shared view of entertainment" often shaped by television sit-coms, thus 'representing' an incurious reader.

The nub of the argument is that book reviewers are gentle and fear retaliation for delivery of a bad review. This retaliatory power will surely temper the ferocity of any review, although the social bond between reviewer and author may only be a backcloth to the review. Other, more obvious, stimulants to a mild or enthusiastic review may be at work. The review may accurately reflect the reviewer's opinion of the book. Other reasons for soft reviews may pertain. The sense of 'usefulness' of the book to the reviewer may be influential on the delivered reviews. As will be seen later, practitioner reviewers are frequently more caustic because they are looking for something beyond that which may be seen as useful to an academic audience.

The books reviewed in *CME* from volumes 22 to 24 provided the sample. The reviews are inspected for certain characteristics. These included the style of review, how informative the review was, how supportive is the reviewer of the ideas carried by the book and, the acid test, does the reviewer recommend the reader to buy.

In a small and tightly knit construction-management community, reviewers are seldom unknown. Reviewers need to be authoritative and well informed, and these conditions come about by mixing with others in the discipline. Inevitably, we will be invited to review books by friends and the need to retain critical faculties in such circumstances is paramount.

STYLE OF REVIEW

Whilst there is limited evidence of a set of rules for book reviewing, certain axioms may be stated:

- Whilst reviews are seen as a part of marketing, they should not be ‘selling’ to the reader.
- The reviewer should not show off their knowledge but offer an opinion on the work under review
- A degree of academic and ascetic judgement must be shown.
- The reviewer must be cognisant of the stage of career development of the author.
- Finally, is the book worth buying?

These axioms are often prosecuted through the medium of metaphor and wit.

These are the artifices that are used frequently by reviewers; metaphors are used to convey an impression of the work under review. Such a vehicle enables wit to embellish the review.

Of the 52 reviews constituting the data for this paper, only one used the metaphor technique to convey to the reader an understanding of what a book was about. Indeed, only two reviews drew upon sources beyond the book itself. Of these two, only one referred to concepts beyond the scope of the construction literature. Why might this be the case? A number of reasons come to mind. Firstly, the audience for reviews appearing in more mainstream publications are rather different to that of *CME* where the audience will be largely drawn from ones peers. The reviewer may feel exposed if a jocular style is presented. Secondly, a more flippant review may be taken as insulting to the quality of work under review. Reviewers may naturally be cautious about giving slight to colleagues in what is a relatively tight knit community. Thirdly, the commissioning process for reviews will be different. Books reviewed in the mainstream press will have been selected by the literary editor or such like. Such selectivity is unlikely to be the case in *CME*. Whilst editors may select reviewers who will deliver an interesting and lively review, the scope for this is likely to be diminished in the case of CME. Fourthly, in order to use metaphors there needs to be a commonly understood culture, and whilst newspapers will have an international audience, they are produced largely for domestic consumption. The international span of *CME* may obviate against the use of metaphors in reviews since a common understanding of what is being signalled by a metaphor may not be obvious. Finally, do we have the confidence to break out of the restrictions of academic writing?

DOMINANT CONTROL WITHIN A COMMUNITY OF PRACTICE

The concept of retaliatory power with respect to how complementary or derogatory a review is has been noted above. The CME community is without doubt international in nature and through associated activities (i.e. ARCOM, CIB conferences, sister journals) its participants are aware of key players within interest groups. As the community evolves in membership, degree of participation and scholarly interests, tensions between members may be evident. Although rarely explicit, such tensions are normally played out through critical attacks on research activity (i.e. validity of methodology, conclusions etc.) that is often reflected in the process and outcome of peer-reviewed journal papers. This tension may also be explicit regards the success of funded research proposals and in doing so suggests another control factor within the community.

If we are to consider the research groups responsible for work in specific topics (i.e. procurement, culture, innovation, project management, finance, human resource management) then participants within the community would be likely to name two to three of those who hold influence in such scholarly work. It could be considered that these individuals have a referent power within the community that is of particular importance with regards book reviews. However, an excessive number of reviews glorifying each others work has the potential to lead to "the scene that celebrates itself" whereby cliques within the community are reliant on each others positive endorsement. Employing construction practitioners to undertake reviews would be a useful approach in reducing this potential bias.

THE PRICE OF BOOKS

A crude analysis of the price per page of books across a range of publishers is presented. But this does not answer the question – what is a fair price? Again, Orwell (1968b) makes some interesting points when reviewing the contribution of Penguin books to the publishing world. He notes, "If you have £2 to spend on books, and the book price is £1, you may buy two books. But if the books are 20p, you are unlikely to buy 10 books, because you don't want as many as that. Saturation point has been reached before you get to 10. You may buy three books and spend the other £1.40 on something else. Hence, the cheaper books become, the less money is spent on books. This is to the advantage of the reader and trade as a whole, but for the publisher, bookseller and author it is a disaster."

Table 1 shows large differences in the price per page of books from different publishers. The data takes no account of the variables that will shape the price: issues such as hardback and soft back editions, the number of any previous editions, the quantity of graphic and tabulated material etc. These production-related issues will be influenced by the perception of the publisher of how well the book will sell – matters such as quality of writing and the 'must-have' utility of the information presented by the book. For example, a copy of the Building Regulations is likely to sell well because it is a 'must-have' book for every profession, whilst a book such as 'finite element analysis in designing tall structures' (a made up title) is seen to have fewer sales since its imparted knowledge is likely to be understood by fewer people. These factors may guide publishers to a price but Table 1 does not explore the cost of production for each book. These may vary greatly. It is presented mainly as a matter of passing interest and something that may stimulate further investigation.

Table 1: Publishers and prices of books

Publisher	No. of books	Sample	Average Price p/page	Range of Price p/page
Blackwell	23	22	£0.12	£0.05–0.20
Spon	6	4	£0.16	£0.16–0.18
Various university presses	5	4	£0.11	£0.07–0.19
Thomas Telford	4	3	£0.24	£0.20–0.29
Palgrave MacMillan	3	3	£0.06	£0.05–0.07
CIRIA	2	2	£0.38	£0.31–0.46
Professional bodies & charities	2	2	£0.34	£0.26–0.62
Other publishers with one publication	9		£0.17	£0.02–0.45

THE TRENDS IN WHAT IS REVIEWED

Whilst a more convincing story could be told by using publishers' catalogues as a database, it is interesting to review the trends of the specialist books that have come under review in *CME*. The purpose of this analysis is to see if certain subjects grow or diminish in popularity over the five years.

The range of subjects is shown in Table 2. Volume 20 reviews the most books and so, unexpectedly, the range of subjects covered is the widest with 11 of the 14 categories being covered. The most written about specialism is project management, shortly followed by economics and finance, and sustainability – all three of these categories have books reviewed in every volume within the survey. There are important signifiers of the interests of the construction management community.

If we consider the driving force behind these trends, it is evident that academia has continued to seek publications that reinforce the need for inquiry. This is self sustaining and perhaps reflects the belief that such textbooks inform practice within industry as opposed to documenting it. Of course, one could not argue that these books are vehicles for dissemination. However, it is rare occurrence to hear of any construction textbook described as seminal or groundbreaking. This is in contrast to other texts (i.e. Womack *et al*.'s (1991) *The Machine that Changed the World: The Story of Lean Production)* that, rightly or wrongly, have been regarded as essential reading for construction CEOs.

WRITTEN OR EDITED? BY WHOM?

There has been a trend towards 'editing' in preference to 'writing' books over the period under review. Within the sample, eight books carry the notation that the writers have edited the volume and the underlying trend is that edited books appear in the later years of the sample (three of the eight in 2005). The editorial roles are conducted invariably by academics. Yet, practitioners are active in several books: practitioners wrote 10 of the sample, whilst academics contributed 32 (10 books were unassigned in the category as the author's affiliation was not available). Only one book could be codified as being produced by an academic and practitioner working together. This is surprising given the exhortation by government, industry and academics that research partnerships are needed between practice and the academy. The output of jointly presented research papers may have flourished in this environment, though this has not transferred to scholarship.

EVALUATION OF REVIEWS

The dominance of academics amongst the reviewers is overwhelming: 40 of the reviews are presented by academics and only seven by practitioners. Five reviews could not be categorized. The practitioners are notably more hostile when compared to academics. When tested against the three criteria that had been selected to evaluate the reviews (informative, supportive and recommended), only eight affirmative reviews out of 21 were given (38%) and five reviews could be classed as hostile to the work under consideration.

This compares to the academic sample, which reported 88 approvals against 32 negative opinions (73% approvals) assigned to the informative, supportive, recommended criteria. Reviewers from the academic group did not recommend 10 of the 40 books reviewed. Practitioners did not recommend four of the seven books under scrutiny. Those with unknown affiliations were receptive to the book under review 12 times out of 15 (80% approvals).

Although these are small samples, there are clear differences between the perceptions of reviewers from industry and those from academia. Why might this be? Several factors may be at work. The first explanation may lie with the dual role of author and reviewer. At least 19 of the reviewers are known to have authored books. This section of the reviewing population was particularly sympathetic of others, providing 41 approvals out of a possible 57 (72%). Knowing that the boot is to be on the other foot on some future occasions may act as a powerful brake on acerbic criticism. Secondly, the social relationships that exist inside a small and tight knit academic community may deter a ‘no-holds-barred’ approach. Even if reviewers are not authors or have no intentions to be authors, the sense of being part and needing to be part of the academic community may blunt critical comments. Clearly, the practitioner reviewers do not feel constrained by this social cohesion since their reviews are much harsher.

CONCLUSION

The review of new books within learned journals provides a community of practice with an opportunity to disseminate new knowledge. The purpose of a review is to provide an objective critique of the works whilst seeking to fulfil several, often competing objectives. The book authors, editors wishing for a healthy recommendation, as are the publishers, whilst the academic community at large may be looking for possible course textbook recommendation. What is unknown is the degree to which reviews are tempered as a result of the social and professional bonds within the *CME* community. Aside from the social issues, it may be that academics write books to be read by other academics and so a sympathetic review is a statement of confirmation of membership of a ‘tribe’. Although no evidence of such bias is evident, it would be naive to ignore this as a potential control factor, explicit or implicit, over the community. As was noted, the few practitioners who were commissioned to undertake reviews were notably less supportive in their critique. Perhaps this suggests the usefulness rating of textbooks for this group is wanting. This would be a disappointing conclusion and particularly so given that the Fairclough (2002) report sought to ensure more substantial collaboration between industry and academia. One solution that may find an appropriate home would be for CME to employ dual reviewers with both practitioner and academic seeking to rate the textbook over such variables as ‘innovative’ ‘potential for knowledge transfer’ and ‘usefulness for academics and practitioners’. This would provide some cover to the academic within the CME community – akin to the anonymity of a soldier using one bullet in a firing squad (albeit with only two actors) – and may encourage a deeper critique.
