#### 42 Abstract

Satellite data are increasingly used to provide observation-based estimates of the effects of aerosols 43 on climate. The Aerosol-cci project, part of the European Space Agency's Climate Change 44 Initiative (CCI), was designed to provide essential climate variables for aerosols from satellite data. 45 Seven algorithms, developed for the retrieval of aerosol properties using data from AATSR (3), 46 MERIS (3) and POLDER, were evaluated to determine their suitability for climate studies. The 47 primary result from each of these algorithms is the aerosol optical depth (AOD) at several 48 wavelengths, together with the Ångström exponent (AE) which describes the spectral variation of 49 50 the AOD for a given wavelength pair. Other aerosol parameters which are possibly retrieved from satellite observations are not considered in this paper. The AOD and AE were evaluated against 51 independent collocated observations from the ground-based AERONET sun photometer network 52 and against "reference" satellite data provided by MODIS and MISR. Tools used for the evaluation 53 were developed for daily products as produced by the retrieval with a spatial resolution of 54 10x10km<sup>2</sup> (Level 2) and daily or monthly aggregates (Level 3). These tools include statistics for L2 55 and L3 products compared with AERONET, as well as scoring based on spatial and temporal 56 57 correlations. In this paper we describe their use in a round robin (RR) evaluation of four months of 58 data, one month for each season in 2008. The amount of data was restricted to only four months because of the large effort made to improve the algorithms, and to evaluate the improvement and 59 current status, before larger data sets will be processed. Evaluation criteria are discussed. Results 60 presented show the current status of the European aerosol algorithms in comparison to both 61 AERONET and MODIS and MISR data. The comparison leads to a preliminary conclusion that the 62 scores are similar, including those for the references, but the coverage of AATSR needs to be 63 enhanced and further improvements are possible for most algorithms. None of the algorithms, 64 including the references, outperforms all others everywhere. AATSR data can be used for the 65

- retrieval of AOD and AE over land and ocean. PARASOL and one of the MERIS algorithms have
- 67 been evaluated over ocean only and both algorithms provide good results.
- 68 Keywords: Aerosol retrieval algorithms, Aerosol optical depth, AATRS, MERIS, PARASOL

# 70 **1. Introduction**

Satellite-based radiometers and spectrometers have been used for the observation of aerosol 71 properties from space since more than three decades (e.g., de Leeuw and Kokhanovsky, 2009; Lee 72 et al., 2009). The data have increasingly been used for purposes such as air quality assessment (Hoff 73 and Christopher, 2009; van Donkelaar et al., 2010), emission estimates (Huneeus et al., 2012), 74 forest fires applications (Kaufman et al., 1998; Labonne et al., 2007, Sofiev et al., 2009), 75 atmospheric correction of oceanic (Müller et al., 2013) and terrestrial (Zelazowski et al., 2011) 76 observations, etc.. In this paper we focus on the use of satellite instruments to provide aerosol 77 78 observations for climate and climate change studies. In particular seven aerosol retrieval algorithms using data from different instruments, or a combination of instruments, are evaluated for their 79 suitability to produce climate-relevant aerosol parameters. This study was undertaken in the context 80 81 of the European Space Agency (ESA) Climate Change Initiative (CCI) (Hollmann et al., 2012) project Aerosol-cci (Holzer-Popp et al., 2013). Aerosol-cci focuses on European instruments and 82 83 the results are evaluated against non-European instruments such as the Moderate Resolution Imaging Spectroradiometer (MODIS), the Multi-angle Imaging SpectroRadiometer (MISR), and 84 model predictions. 85

After a brief introduction to aerosols, their effects on climate, the use of satellite-based instruments to obtain information on aerosols, algorithms developed for this purpose and a short overview of the Aerosol-cci project, the participating aerosol retrieval algorithms will be summarized followed by a summary of recent improvements which are described in detail in Holzer-Popp et al. (2013). The main focus of this paper is on methods used for the validation and evaluation of the aerosol retrieval algorithms in a round-robin (RR) exercise, the protocol used in this RR exercise to select the most suitable algorithm, or combination of algorithms, and the results from this exercise.

93 Atmospheric aerosol is formally defined as a suspension of particles and/or droplets in air. In the 94 following we neglect the surrounding medium and refer mainly to the particles which are

characterized by a certain radius (specified at a certain relative humidity, RH: dry (RH < 30-40%95 (WMO-GAW, 2003), at RH=80%, or their in situ value at ambient RH. Satellites observe aerosol 96 properties in situ, usually integrating over the whole atmospheric column in which both RH and 97 aerosol concentrations may vary strongly. Ground-based measurements are prescribed to be made at 98 dry conditions (WMO-GAW, 2003). Aerosol particles may have sizes ranging from a few nm to 99 several tens of um, can be composed of a wide range of chemical species (organic matter, inorganic 100 salts) which are either internally mixed (different species occur in one particle) or externally mixed 101 (each particle is composed of one single species) and mixed forms of these. Each size range may 102 have its own physical and chemical properties and based on these different 'modes' are considered, 103 such as cluster (a few nm), nucleation (ca. 5 nm), Aitken (some tenths of nm), accumulation (a few 104 hundreds of nm) and coarse (larger than 500 nm) particle modes, where the numbers in parenthesis 105 indicate dry mode radius (see eq. 1). The particle size distribution describes the variation of the 106 particle concentrations with size. The concentrations may be as large as  $10^4$  to  $10^5$  cm<sup>-3</sup> for 107 accumulation mode particles in polluted conditions or as small as 10<sup>-5</sup> cm<sup>-3</sup> for the largest particles 108 109 (radius some tens of  $\mu$ m). Total concentrations, i.e. integrated over the whole size distribution, may vary from a few 10s cm<sup>-3</sup> in very clean conditions to up to  $10^5$  cm<sup>-3</sup> in polluted conditions. Particles 110 can be directly produced by, e.g. mechanical (wind-blown dust, sea spray aerosol), biological 111 (pollen) or combustion (traffic, industry, fires) processes, or they can be produced from precursor 112 gases by gas-to-particle conversion processes and nucleation. Atmospheric aerosol particles have a 113 life time varying from hours to days, depending on their size, during which they undergo physical 114 and chemical changes which in turn changes their chemical composition and their optical and 115 physical properties. Of importance for climate and climate change are particles with dry radii 116 between ca. 30 nm to several µm because these particles are most effective for scattering of 117 radiation in the UV/VIS part of the solar spectrum, and because these particles can be activated to 118

become cloud condensation nuclei (CCN) and thus affect cloud macro- and micro-physicalproperties which in turn affects cloud reflectance and precipitation.

Aerosol size distributions are commonly approximated by multi-modal log-normal size
distributions (Seinfeld and Pandis, 1998), i.e.:

123 
$$\frac{dN(r)}{d\ln r} = \sum_{i=1}^{2} \frac{N_i}{(2\pi)^{1/2} \ln \sigma_i} \exp\left(-\frac{\left(\ln r_i - \ln \bar{r}_{g_i}\right)^2}{2\ln^2 \sigma_i}\right),$$
(1)

where each log-normal mode is defined by three parameters: aerosol number concentration  $N_i$ , 124 number mode radius  $\bar{r}_{gi}$  and (geometric) standard deviation  $\sigma_i$ . Only aerosol particles with sizes 125 larger than about 0.05 µm in radius (in situ) are optically active and therefore in satellite retrievals 126 only these larger sizes need to be represented. As there is a cross-section minimum at radii of about 127 0.5 µm and the aerosol composition above and below that size is usually quite different, in aerosol 128 retrieval the size distribution is usually described as bi-modal rather than mono-modal. The smaller 129 size mode (aerosol radii  $< 0.5 \,\mu$ m) of the assumed bi-modal distributions is referred to as fine mode 130 and the large size mode (aerosol radii  $> 0.5 \mu$ m) is referred to as coarse mode. 131

Aerosols have a large impact on climate through their direct effects (scattering and absorption of 132 solar radiation) and indirect effects (through their effect on cloud microphysical properties) on the 133 radiation balance in the earth system. Studies on the effect of aerosols on climate were traditionally 134 made by using chemical transport models (CTM) or global climate models (GCM), or their regional 135 versions. In the last decade satellite observations have increasingly been used to provide 136 observation-based estimates of the effects of aerosols on climate (Yu et al., 2006; Thomas et al., 137 2012). Satellite observations offer the advantage of large spatial coverage with the same instrument 138 and technique as implemented in an instrument-specific retrieval algorithm, at the cost of accuracy 139 and temporal coverage offered by most ground-based observations. However, ground-based 140 observations are representative for only a relatively small area around the observation site, mainly 141 concentrated in certain areas, i.e. Europe, North America and some parts of other continents, while 142

the oceans are sparsely covered. Satellite observations offer in principle global coverage, dependingon swath width, in about one day to a week.

The effect of aerosol particles on solar radiation are determined by the particle size distribution and 145 their size-segregated chemical composition, which together determine the angular scattering 146 (expressed as the phase function), absorption and single scattering albedo (ssa, the ratio of 147 scattering and the sum of total scattering and absorption), and the vertical variation of these 148 parameters. Scattering and absorption together determine the extinction of solar light by aerosol 149 particles and the extinction coefficient is the sum of the scattering and absorption coefficients. 150 Changes in global, regional and local effects of aerosol particles can thus be determined by changes 151 in these properties or a combination of them. The basic aerosol parameter retrieved from satellite-152 based observations is the aerosol optical depth (AOD, or  $\tau$ ), i.e. the column-integrated extinction 153 coefficient specified for a certain wavelength,  $\lambda$ . AOD time series could thus be used to determine 154 155 trends indicating changes on regional to global scales. However, this requires that AOD can be determined with sufficient accuracy to provide statistically significant trends. Such requirements 156 have been formulated by GCOS (ref) and were further formulated as part of the aerosol-cci project 157 described see in Section 2. In addition to AOD, other parameters are sometimes made available 158 from satellite observations with a varying degree of reliability and accuracy. These parameters 159 include the Ångström exponent (AE) describing the wavelength dependence of the AOD, the fine 160 mode fraction (FMF) describing the contribution of particles with dry radii smaller than 0.5 µm to 161 the total AOD, coarse mode fraction (CMF) describing the contribution of larger particles to the 162 total AOD, aerosol type (i.e. parameters describing the aerosol size distribution and optical 163 properties), absorbing aerosol index (AAI), ssa, absorbing aerosol optical depth (AAOD), aerosol 164 layer height. The determination of these other parameters usually requires an AOD exceeding a 165 certain value to obtain a reasonable value (e.g., Holzer-Popp et al. 2002a; 2002b; Kahn et al., 2010) 166

Instruments used for aerosol retrieval include spectrometers and radiometers with one or more 167 168 wavebands in the UV/VIS and NIR parts of the electromagnetic spectrum, i.e. those wavelengths most sensitive to the scattering of solar light by aerosol particles, with one or more viewing 169 170 directions and in some cases with information on polarization of the scattered light. Wavelengths in the thermal infrared (TIR) are mainly used for cloud detection, i.e. together with shorter 171 wavelengths they provide information on the occurrence of clouds which hinders the retrieval of 172 aerosol properties; thus cloud-contaminated pixels are discarded from aerosol retrieval. Wavebands 173 in the NIR and TIR also provide information on larger aerosol particles such as volcanic ash and 174 desert dust. A challenge is to discriminate between desert dust and clouds, i.e. desert dust, although 175 176 considered aerosol, is often inadvertently classified as cloud and thus discarded in the aerosol retrieval process. In addition, satellite-based lidars are used to provide information on aerosol 177 properties. An overview of instruments and algorithms used for the retrieval of aerosol properties 178 179 from space is provided in Kokhanovsky and de Leeuw (2009) and de Leeuw et al. (2011).

The first instruments which have been used for the retrieval of aerosol properties were launched 180 over three decades ago and thus have the potential to be used for the provision of long time series of 181 aerosol properties and for the analysis of aerosol trends. However, there are issues related to the use 182 of different instruments, which may not be exactly the same, and their calibration. Furthermore, 183 most instruments used for aerosol retrieval were not designed for that purpose and the information 184 they provide is sub-optimal. Exceptions are MODIS, MISR and POLDER (POLarization and 185 Directionality of the Earth's Reflectances). Nevertheless, instruments like the MEdium Resolution 186 Imaging Spectrometer (MERIS), ATSR-2 (Along Track Scanning Radiometer) and AATSR 187 (Advanced ATSR), SeaWiFS (Sea-viewing Wide Field-of-view Sensor), OMI (Ozone Monitoring 188 Instrument) and AVHRR (Advanced Very High Resolution Radiometer), as well as instruments 189 such as SEVIRI (Spinning Enhanced Visibile and Infrared Imager) flying on geostationary satellites 190 are currently used for aerosol retrieval. However, the results are often less accurate in comparison 191

with dedicated aerosol retrieval instruments. This may be somewhat surprising in cases where the instrument characteristics are not limiting factors. For instance, the ATSR-2 / AATSR instruments should potentially provide good results because of the dual view capability which allows for more effective decoupling of the surface and atmospheric contributions to the top of atmosphere (TOA) radiance than is possible with a single view, and because of the availability of wavebands from the visible (VIS) to the thermal infrared (TIR) facilitating effective cloud screening.

198 All instruments, also those dedicated for the retrieval of aerosol and cloud properties, do provide insufficient information to accurately determine all relevant aerosol properties, i.e. particle size 199 distribution, size-dependent particle shape and chemical composition, mixing state, from which the 200 201 optical properties could be determined. This is in part due to the lack of vertical resolution of spectrometers and radiometers. These instruments observe the effect of aerosol particles integrated 202 over the whole atmospheric column while usually not only their concentrations may change with 203 204 height but also their chemical composition. In addition, as indicated above, particle sizes change with varying relative humidity. Furthermore, the atmosphere may be stratified and in disconnected 205 206 layers with different origin and different history the aerosol properties may be different. This situation is further complicated by the occurrence of absorbing particles, the effect of which on the 207 AOD depends on the altitude at which they occur. 208

As a result, the retrieval problem is underdetermined, i.e. there are more unknowns than 209 independent pieces of information to solve the radiative transfer equations and assumptions need to 210 be made. These include assumptions on the aerosol properties, using simplified descriptions of size 211 distributions and optical parameters and aerosol layer height. Furthermore the treatment of the 212 surface is very important, in particular over reflecting surfaces where the surface contribution to the 213 upwelling TOA radiance may be as strong as, or even much stronger than, the atmospheric 214 contribution. Over ocean the retrieval is often relatively simple because the ocean surface is dark at 215 wavelengths in the NIR and an ocean reflectance model is often used to account for effects such as 216

sun glint, waves, whitecaps or chlorophyll. Over land, forests are often relatively dark at shorter
wavelengths in the UV/VIS and at wavelengths in the UV all surfaces are dark. The latter has been
used in the MODIS deep blue algorithm (Hsu et al., 2004). However, when UV wavelengths are not
available or over brighter surfaces, other assumptions need to be made.

Aerosol retrieval algorithms utilizing the radiance measured at the top of the atmosphere at different 221 wavelengths, viewing angles and polarization, have been developed to optimally use the available 222 223 information, based on different physical principles, cf. Kokhanovsky and de Leeuw (2009) and de Leeuw et al. (2011) for detailed descriptions of algorithms used for the retrieval of aerosol 224 properties over land. However, comparison of the AOD obtained from different algorithms may 225 vary widely and some algorithms may perform better than others. These differences are regionally 226 dependent and there is no single algorithm that outperforms all others everywhere (cf. Kahn et al., 227 2009; van Donkelaar et al., 2010). The MODIS dark target algorithm (Levy et al., 2007) is most 228 229 often used. It has been validated (Levy et al., 2010), provides two observations daily, each of them with near-global coverage, and the data are easy to access. Nevertheless, there are gaps, e.g. no data 230 231 are available over bright surfaces such as deserts.

The basis for the assessment of aerosol retrieval algorithms is usually the comparison of the 232 retrieval results, in particular AOD and AE, with independent data provided by AERONET, a 233 federated network of ground-based sun photometers (Holben et al., 1998). Ground-based sun 234 photometers provide accurate measurements of AOD (uncertainty ~0.01-0.02, Eck et al., 1999) 235 because they directly observe the attenuation of solar radiation without interference from land 236 surface reflections. The comparison of, e.g. MODIS and MISR AOD with AERONET data shows 237 that the results from each instrument are within specification but yet there are differences between 238 them (Kahn et al., 2009). The performance of most of the European sensors prior to the start of the 239 Aerosol-cci project was much less good than that of, e.g., MODIS or MISR as indicated from a 240 comparison of the AOD retrieved using the baseline algorithms with that obtained from either 241

MODIS or MISR and with the AERONET AOD (Holzer-Popp et al., 2013). It is noted here that AERONET data is well screened for cloud so that it does not provide a good test of how well an algorithm behaves in the case where cloud has not been removed by cloud flagging.

The Aerosol-cci project was designed to provide essential climate variables (ECVs) for aerosols 245 from satellite data (Holzer-Popp et al., 2013). To achieve this, the quality of current satellite aerosol 246 products needed to be assessed and, when the quality was found to be insufficient, improved. 247 248 Participating algorithms, focusing on European instruments, are listed in Section 3, where also brief descriptions are provided of the most important characteristics of each algorithm. Other instruments 249 (MODIS, MISR) and algorithms were used for comparison, and this comparison provided a 250 251 measure for the performance of the Aerosol-cci algorithms and their subsequent improvement. The initial focus of the Aerosol-cci project was on understanding differences between different 252 algorithms as a basis for their improvement. The baseline algorithms were those that existed at the 253 254 start of the project and improvements were measured with respect to these, using several different methods described in Section 5. Tests were made for data from a single month (September 2008) as 255 256 described in Holzer-Popp et al. (2013). The best version, as decided by each earth observation (EO) team for their own algorithm based on these tests, was used in a round robin (RR) test which 257 encompassed four months in 2008 (March, June, September and December) representing the 258 different seasons. This paper describes the RR tests and results. Based on the RR exercise, the best 259 possible algorithm, or combinations of algorithms, will be selected to produce the global AOD for 260 the whole year 2008 for further evaluation as regards the use of the products in climate studies. For 261 more information on the aerosol-cci project, see: http://www.esa-aerosol-cci.org/. 262

263 2. The Aerosol-CCI project

The Aerosol-cci project is a consortium including 14 partners coordinated by DLR with FMI providing the science co-leader. The consortium consists of three teams. The EO team is responsible for algorithm development and improvement, the validation team is responsible for the

validation and evaluation of the retrieval products, and the system engineer team is responsible for 267 268 the actual processing of the data series and system design. The validation team is independent from the EO team (different partners) which ensures an independent and unbiased evaluation of the EO 269 270 products. Furthermore, the validation team includes representatives of the global climate modelling community through AEROCOM and their feedback ensures that products will indeed be useful for 271 climate studies. This aspect has proven to be of crucial value for the improvement of the retrieval 272 273 algorithms. The system engineering team brings the experience of data centres and experience with data format and data access. The Aerosol-cci project started in July 2010 and has duration of 3 years 274 with a potential extension to 6 years. 275

# 276 **3. Aerosol retrieval algorithms**

The aerosol retrieval algorithms included in the Aerosol-cci project, Table 1, use data from AATSR 277 and MERIS, both flying on ESA's Environmental satellite ENVISAT (2002-2012), and POLDER, 278 flying on PARASOL which is part of NASA's A-train constellation. Aerosol-cci includes 279 algorithms which use one single instrument and the SYNAER algorithm which synergistically uses 280 AATSR and SCanning Imaging Absorption spectroMeter for Atmospheric CHartographY 281 282 (SCIAMACHY). These algorithms provide information on column-integrated aerosol properties such as AOD and additional information which differs for each algorithm. An overview is presented 283 in Table 1. In addition, the Ozone Monitoring Instrument (OMI) provides information on the 284 aerosol absorbing index (AAI) and the Global Ozone Monitoring by Occultation of Stars (GOMOS) 285 provides information on stratospheric aerosol profiles. 286

Each of these algorithms is extensively described in their respective ATBD (algorithm theoretical baseline document) provided on the Aerosol-cci website (<u>http://www.esa-aerosol-cci.org/</u>) and references provided in these. Brief summaries of the essential characteristics of each algorithm are provided below.

#### 291 AATSR ADV and ASV

The ATSR-2/AATSR dual view aerosol retrieval algorithm, ADV, is based on Veefkind et al. 292 (1998). The main feature of the ATSR instruments is the dual view which in ADV is used to 293 effectively eliminate the contribution of the surface reflection to the TOA reflectance, using the k-294 ratio approach, and retain only the atmospheric path radiance. The k-ratio approach uses the ratio of 295 the reflectances measured in the forward and nadir views, based on Flowerdew and Haigh (1995). 296 The k-ratio is evaluated for the 1.61 µm channels and is assumed to be wavelength-independent. 297 298 Over bright surfaces this approximation may not apply and the method is therefore limited to TOA reflectances at 1.6 µm wavelength of smaller than 0.45 at nadir. Furthermore, the contribution of 299 aerosols to the AOD at 1.61 µm is in first approximation assumed to be negligible, but is given a 300 301 value during the next iteration steps. This assumption does not hold in the presence of coarse mode aerosol such as desert dust. Aerosol retrieval over ocean is based on the single view algorithm, 302 ASV, developed by Veefkind and de Leeuw (1998). The ocean surface is assumed dark at 303 wavelengths in the NIR and an ocean reflectance model is used to correct for effects due to 304 chlorophyll and whitecaps. Pixels for which the AATSR L1b GBT data indicates sun glint are 305 306 excluded form retrieval. ADV and ASV use the cloud mask described by Robles-Gonzalez (2003) (see also Curier et al., 2009), with a post-processing method based on comparison of neighbouring 307 pixels in a 3x3 pixels (L2) area. The post-processing effectively eliminates spatial inhomogeneity's 308 309 such as those due to previously undetected clouds and cloud edges. The path radiance is used to retrieve the aerosol properties using a LUT approach with a combination of aerosol components 310 described in Section 4. The mixing ratio of these aerosol components, and thus the size distribution 311 and optical properties, is varied to match the reflectances at each of the 3 (ADV) or 4 (ASV) 312 wavelengths in the VIS and NIR. ADV and ASV products are AOD at 3 (ADV) or 4 (ASV) 313 wavelengths, AE (needs AOD (550 nm) > 0.2 to obtain reasonable results) and mixing ratio, with 314 ssa and surface albedo as research products. Default resolution is 10x10 km<sup>2</sup>, but also 1x1 km<sup>2</sup> is 315

- used in certain studies. The latest version of ADV/ASV including many improvements made at
- FMI/UHEL and uncertainty characterization is described in Kolmonen et al. (2013).

#### 318 AATSR ORAC

The Oxford-RAL Retrieval of Aerosol and Cloud (ORAC V1) algorithm is an optimal estimation 319 (OE) retrieval scheme designed to provide estimates of aerosol optical depth and effective radius, 320 cloud top pressure, height and temperature, cloud particle effective radius, cloud optical depth and 321 cloud type (generally liquid water or ice) from multispectral imagery (Thomas et al. 2009, Poulsen 322 323 et al., 2011; Sayer et al., 2011). The method fits all the shortwave forward and nadir radiances simultaneous using a forward model based on the DISORT radiadive transfer code (Stamnes et al. 324 1998). It is worth noting that the simultaneous retrieval of all state parameters provided by the OE 325 326 method ensures that a physically consistent and numerically optimal estimate of the state is produced. The quality of fit to the radiances allows the quality of the retrieval to be judged a 327 posteriori. In addition the error in the retrieved aerosol parameters is estimated by propagating both 328 the measurement and forward model uncertainties into state space. Note that the dataset described 329 here was produced by the ORAC V1 algorithm an *a priori* surface BRDF is set using MODIS 330 331 MCD43B BRDF products (Jin et al., 2003) over land and an ocean surface reflectance model over 332 the ocean (Sayer et al., 2010). More recent processing with an updated surface model is currently under evaluation but initial indications show a substantial improvement when compared to V1. 333

### 334 SU ATSR algorithm

The SU-ATSR algorithm has been developed at Swansea University for estimation of atmospheric aerosol and surface reflectance for the ATSR-2 and AATSR sensors. Over land, the algorithm employs a parameterised model of the surface angular anisotropy, and uses the dual-view capability of the instrument to allow estimation without a priori assumptions on surface spectral reflectance. Over ocean, the algorithm uses a simple model to exploit the low ocean leaving radiance at red and infra-red channels at both nadir and along-track view angles. The surface models are used to invert the 6SV model (Kotchenova, et al., 2006; 2007) to perform retrieval at 10km resolution. The algorithm has been implemented on the ESA Grid Processing on Demand (GPOD) system to allow global processing and free download of AOD and surface reflectance. The method is documented in North et al. (1999), North (2002), Grey et al. (2006a; b) and Bevan et al. (2009, 2012).

345 SYNAER

The synergistic aerosol retrieval method SYNAER delivers aerosol optical depth (AOD) and an 346 estimation of the type of aerosols in the lower troposphere over both land and ocean by exploiting a 347 348 combination of a radiometer and a spectrometer. The type of aerosol is estimated as percentage contribution of 4 representative aerosol components (sea salt, mineral dust, weakly absorbing 349 accumulation mode and strongly absorbing accumulation mode aerosol). The high spatial resolution 350 351 including thermal spectral bands of the radiometer permits accurate cloud detection. The SYNAER aerosol retrieval algorithm comprises of two major parts. In step 1 a dark field method exploits 352 single wavelength radiometer reflectances (at 670 nm over land, at 870 nm over ocean) to determine 353 36 values of the aerosol optical depth and surface reflectance over automatically selected and 354 characterized dark pixels for a set of 36 different pre-defined boundary layer aerosol mixtures. In 355 356 step 2 the parameters retrieved in the first step are used to simulate spectra for the same set of 36 different aerosol mixtures with the same radiative transfer code after spatial integration to the larger 357 pixels of the spectrometer. A least square fit of these calculated spectra at 10 wavelengths to the 358 359 measured spectrum delivers the correct AOD value (the one AOD retrieved in step 1 for the aerosol type selected in step 2) and - if a uniqueness test is passed - the most plausible spectrum and its 360 underlying aerosol mixture. (Holzer-Popp et al. 2002a; 2008). Using a combination of 2 instruments 361 with different scan patterns SYNAER can only provide global cloudfree coverage every 12 days 362 and with large pixels of 60x30 km<sup>2</sup>. However the combination of the 2 instruments has the potential 363 to provide aerosol type information (qualitatively shown in Holzer-Popp et al., 2008). Although 364 these method-inherent limitations mean a significant drawback in comparison to AATSR AOD 365

366 products, SYNAER has been included into the Aerosol cci project in order to qualify and improve

its quantitative AOD results and thus eventually strengthen the aerosol type information.

### 368 MERIS ESA Standard

The MERIS standard aerosol retrieval over land algorithm was designed to work over Dense Dark 369 Vegetation (DDV) targets (Santer et al., 1999, Ramon and Santer, 2001). A set of DDV 370 Bidirectional Reflectance Function (BRF) models was assembled for 11 different biomes on Earth. 371 DDV detection is based on a threshold on the Atmospherically Resistant Vegetation Index (ARVI) 372 373 computed from Rayleigh corrected reflectances at 443, 665 and 865 nm. As DDV spatial cover is low, the aerosol inversion was extended to brighter surfaces called Land Aerosol Remote Sensing 374 (LARS) targets (Santer et al., 2007). LARS spectral albedo can be predicted as it is linearly related 375 376 to ARVI. Slopes and offsets of these linear regressions are stored in Look Up Tables for 1°x1° boxes and on a monthly basis. The aerosol retrieval consists in the inversion of the AOD at 443 and 377 665 nm that allow to reproduce the measured TOA reflectances at 443 and 665 nm using pre-378 calculated aerosol scattering functions for aerosol models described by a Junge Power-Law (JPL) 379 size distribution and a constant refractive index of 1.45-0.0i. The outputs of the algorithm are the 380 381 AOD at 443 nm and the aerosol Ångström exponent derived between 443 and 665 nm.

Cloud contamination is the biggest issue of the product that is delivered at the same spatial resolution as the level 1B data (i.e. 1.2 km). The product, with a good spatial coverage now, has been validated only for the AOD at 443 nm. The Ångström exponent is not validated since the retrieved AOT at 665 nm is noisy. It is mandatory to move toward spatial resolution of 10x10 km<sup>2</sup> for the aerosol product in order to reduce cloud contamination and enhance the Signal to Noise Ratio (SNR) for the Ångström exponent retrieval. Finally there is a need for improving the LARS BRDF model.

# 389 MERIS ALAMO

390 The MERIS ALAMO (Aerosol Load and Altitude from MERIS over Ocean) algorithm has been

primarily developed for aerosol altitude retrievals using MERIS data. Necessary inputs for altitude 391 392 retrievals, such as aerosol optical properties, are derived in a first step with an initial assumption on the layer altitude. The cloud masking and AOD retrieval schemes are a close adaptation of the 393 MODIS algorithm (Tanré et al, 1997; Remer et al., 2005), using only the following MERIS bands: 394 510, 560, 665, 753.75 and 865 nm. Due to spectral characteristics of MERIS, ALAMO is limited to 395 a maximum wavelength of 865 nm and only two pieces of information on aerosol properties can 396 therefore be retrieved instead of three parameters with MODIS. MERIS aerosols products are 397 retrieved with a spatial resolution of 10x10 pixels (12x12 km<sup>2</sup>). This resolution allows (i) an 398 adequate signal-to-noise ratio (SNR) for a better characterisation of the aerosols type and (ii) 399 400 rejection of pixels considered as non-valid through statistics criteria, in order to ensure the quality of the aerosol product. The aerosol products of ALAMO include the optical thickness and the 401 mixing ratio of fine and coarse modes. Aerosol models used for ALAMO are the same as the ones 402 403 used for the most current version of MODIS products.

In a second step the altitude of the aerosol layer is estimated using the MERIS  $O_2$  A absorption channel and following the algorithm described in Dubuisson et al. (2009). A pixel reclassification is done after the altitude retrieval to remove high thin clouds based on a threshold on altitude and spatial variance of altitude.

### 408 MERIS BAER

The Bremen Aerosol Retrieval, BAER, has been developed to derive spectral AOD from multispectral satellite imagery such as from MERIS over ocean and land. It separates the spectral aerosol reflectance from the surface and Rayleigh path reflectances for the short-wave ( $\leq 0.67 \mu$ m) TOA reflectance over land. Over ocean the whole spectral range of MERIS is utilized for the AOD retrieval.

The surface reflectance is estimated by a linear mixing of vegetation and non-vegetation spectra which are tuned by the Normalized Differential Vegetation Index (NDVI). Bidirectional

Reflectance Distribution Function (BRDF) effects are taken into account using the Raman-PintyVerstraete model (Maignan et al., 2004). Finally BAER derives the target quantity, the AOD, using
LUTs, created with rigorous radiative transfer model calculations, ensuring spectral smoothness for
the retrieval over all channels (von Hoyningen-Huene et al., 2003; 2011).

420 After specific adaptations it could be shown, that the approach is also successfully applicable to 421 retrievals over bright surfaces such as deserts (Dinter et al., 2009)

#### 422 **PARASOL**

423 The PARASOL algorithm is based on look up tables (LUT) of the directional, spectral, and polarized radiances calculated for different aerosol models with different optical thicknesses, size 424 distribution and refractive index. The choice of the models used to build the LUT is a key issue. The 425 426 aerosol size distribution is assumed to be the sum of two contributions, one coming from small spherical (fine mode) aerosols and the other from large (coarse mode) aerosols [Herman et al, 427 2005]. Large particles can be either spherical, non-spherical or a mixture of both. The size 428 distributions of spherical particles (small or large) are described by a log-normal function defined 429 by two parameters, namely, a mean radius and a standard deviation  $\sigma$ . For large non-spherical 430 431 aerosols, an experimental model is implemented in the LUT (Volten et al, 2001). The LUT are built with a radiative transfer code based on successive orders of scattering (Lenoble at al., 2007). The 432 Stokes parameters are calculated at the top of the atmosphere and computations include multiple 433 434 scattering in the atmosphere by molecules and aerosols and take into account the surfaceatmosphere interaction. 435

Over ocean, the inversion scheme mainly uses the normalized radiances in the 865 nm channel, where the ocean color reflectance is zero, and in the 670 nm channel with a constant water reflectance of 0.001. The polarized Stokes parameters at 865 and 670 nm are also used for deriving the best aerosol model. Computations are performed with a rough ocean surface (Cox and Munk, 1954) and a wind speed of 5m/s. The foam contribution is calculated according to Koepke's model

441 (Koepke, 1984) and a constant value of 0.22 for the foam reflectance.

The PARASOL aerosol algorithm over land (Deuzé at al., 2001) is based on a best fit between polarized measurements at 650 and 865nm and LUT's simulated for aerosols within the accumulation mode only. The surface contribution is estimated from a relationship using empirical coefficients adjusted for the different classes of land surfaces according to the main IGBP biotypes and the NDVI (Nadal and Bréon, 1999).

#### 447 **4. Algorithm improvement**

Aerosol retrieval is an underdetermined problem since the number of degrees-of-freedom, i.e. parameters describing the aerosol properties which determine the observed TOA radiances, is smaller than the number of observations. Hence assumptions need to be made. The most important assumptions made in aerosol retrieval concern:

- Cloud screening
- Surface treatment
- Aerosol optical properties and size distribution

455 Aerosol retrieval can only be made for cloud-free sky because the high reflectance of clouds at wavelengths in the UV-NIR interferes with the aerosol reflectance and hence prohibits accurate 456 retrieval of aerosol properties. Therefore, an accurate cloud mask has to be applied to screen all 457 458 pixels for the occurrence of clouds and exclude them from retrieval. Currently all algorithms participating in Aerosol-cci use their own cloud detection procedures as described in section 3 and 459 the literature referenced there. The use of a common cloud flag for similar products is under study 460 (Holzer-Popp et al., 2013). To further eliminate cloud-contaminated data, a post-processing step has 461 been developed to effectively detect cloud edges as described in Section 3 for the AATSR ADV and 462 ASV algorithms. This post-processing step results in a smoothly varying AOD across extended 463 areas without sudden transitions. This post-processing step has been implemented in other 464 algorithms (ORAC, SU) as well. 465

The treatment of the surface and accounting for contributions of surface reflectance to the radiance measured at TOA depends on the instrument properties, and how they are used. An overview of surface treatment and application to different algorithms such as the AATSR algorithms used in Aerosol-cci has been presented in Kokhanovsky and de Leeuw (2009), for MERIS BAER in de Leeuw et al. (2011), and for the other MERIS algorithms in the respective ATBDs. Therefore surface treatment will not be discussed here.

472 Apart from improved cloud screening, most progress has been made in harmonizing aerosol models and their use in the various retrieval algorithms. For the Aerosol-cci project, a simple set of four 473 aerosol components has been developed consisting of two fine mode components, one of which has 474 a complex refractive index representative for weakly absorbing aerosol particles and the other one 475 represents strongly absorbing aerosol particles. The other two components describe coarse mode 476 aerosol components, one with the characteristics of desert dust and the other one describing sea salt 477 478 aerosol. Each component is thus described by a lognormal size distribution, defined by mode radius, effective radius, geometric standard deviation and variance, and by the complex refractive index 479 480 (Table 2).

The two fine mode-types are extremes in terms of absorption and reality (in terms of absorption) is always a combination of these two types. The choice of the fine mode radius is based on an analysis of AERONET sun-photometer data which shows that the most frequent fine mode size (in terms of the effective radius) is near 0.14  $\mu$ m. The coarse mode is dominated by two quite different aerosol types: spherical largely non-absorbing sea-salt and non-spherical absorbing dust. Based on an AERONET probability distribution for the coarse mode, the effective radius was set to 1.94  $\mu$ m for these two coarse mode aerosol types. See Holzer-Popp et al. (2013) for more detail.

The optical properties of aerosol particles are usually calculated by application of a Mie code (Mie, 1908), which applies to spherical particles. However, for dust Mie codes cannot be applied because of the non-spherical shape of dust particles. In Aerosol-cci a T-matrix method was used assuming

randomly oriented spheroids with aspect ratios between 1.44 and 3.0 (Dubovik et al. 2002, Sinyuk 491 492 et al. 2003). Although spheroids may be unable to represent the entire shape complexity for dust, this spheroid method is certainly preferable over methods for spheres. The choice of the refractive 493 index for dust is based on Volten et al. (2001). Observational data (Dubovik et al. 2002, Sinyuk et 494 al., 2003) demonstrate that the dust absorbing strength is wavelength dependent, and decreases from 495 the UV (imaginary refractive index, RFi, near 0.005) to the near-IR (RFi near 0.001). To avoid 496 497 time-consuming computations during the retrieval, radiative transfer is computed in atmospheres with different aerosol components, for discrete AOD values and a range of discrete configurations 498 (e.g., solar zenith angle, viewing angle), and the results are stored in a look-up table (LUT). During 499 500 the retrieval the optical properties for the relevant configuration are obtained by simple extrapolation of the LUT values. 501

For successful retrieval of the aerosol type by using a mixture of the four basic aerosol components presented in Table 2, additional information may be required on relationships between fine and coarse mode, between less and more absorbing fine mode and between dust and sea-salt components in the coarse mode. This information is supplied in terms of monthly  $1^{\circ}x1^{\circ}$ climatological data derived from two sources, modelling and observations.

507 MODELING: Output of 14 different global models with complex aerosol component that 508 participated in AeroCom exercises are combined into 'AeroCom' median maps (Kinne et. al., 509 2006). Based on these median maps, ratios between different aerosol components are defined. Dust 510 and sea salt generally define the coarse mode and sulfate, organic matter and black carbon the fine 511 mode.

512 CLIMATOLOGY: To improve this AeroCom model median, AERONET (Holben et al., 1998) 513 quality data are added in a merging process for AOD, Ångström exponent (describing the AOD 514 spectral dependence) and single scattering albedo (describing the absorption potential). With 515 observational ties data of this 'climatology' are recommended over data from 'modelling'.

This climatology is used as a priori for the occurrence of aerosol types /mixtures, per region and per 516 517 month. In general the coarse mode component selected would be sea salt, except in the presence of desert dust which occurs in certain areas. The choice of the fine mode component would also be 518 based on the climatology and the two fine mode components, with equal microphysical properties, 519 could be mixed to obtain the desired absorption properties (as provided by the ssa in the 520 climatology). Using the occurrence of aerosol types, the retrieval algorithm computes the radiances 521 at the top of the atmosphere which are compared with the satellite measurements. Based on this 522 comparison the aerosol mixtures are adjusted and the procedure is iterated until convergence is 523 reached and the most likely aerosol model providing the measured radiance is selected. With this 524 525 model the AOD is computed. It is emphasized that the climatological AOD is not used in the retrieval process, and the aerosol mixtures are only used as *a priori*, except in sensitivity studies. 526 The actual AOD and aerosol mixtures are retrieved based on the measured radiances at 3 (over 527 528 land) or 4 (over water) wavelengths.

Algorithm improvement was measured by application of the validation and evaluation exercises 529 530 described in Section 5. These exercises were made for only one month, September 2008, a necessary restriction because of the time it takes to run the retrieval with different aerosol mixtures. 531 Success was identified by comparison with the baseline algorithm and successive improvement 532 after implementation of different aerosol models, the use of the AEROCOM median with different 533 degrees of comprehensiveness (i.e. varying from completely free retrieval without any use of the 534 climatology, to a full prescription of the aerosol mixing, and combinations thereof) and different 535 cloud masks. In addition to these experiments, algorithms were also improved as regards coding and 536 debugging and the retrieval products were improved by application of post-processing. Results from 537 this study for 1 month are presented in Holzer-Popp et al. (2013). 538

# 539 **5. Validation and evaluation**

For validation of the retrieval algorithms used in Aerosol-cci, to evaluate their improvement, to select the most suitable algorithm for ECV production, and to assess the achievements as regards meeting user requirements, independent and objective methods are needed leading to quantitative scores. These scores are obtained by comparison with independent data sets, in this case these are provided by the ground-based sun photometer network AERONET (Holben et al., 1998) as described in the introduction. All satellite results, both those participating in the Aerosol-cci RR and the reference satellite data sets, are evaluated versus AERONET.

547 Three principal methods are used based on statistics for Level 2 (L2) and Level 3 (L3) products. In Aerosol-cci L2 products are the daily products as produced by the retrieval with a spatial resolution 548 of 10x10km<sup>2</sup> and L3 are daily or monthly aggregates (also referred to as mean or averaged data) 549 provided on a spatial scale of 1°x1°. The L2 and L3 products are available globally. L2 products 550 contain for each pixel quality flags, or a level of confidence, set by the data provider as well as 551 uncertainty estimates. L3 products contain for each pixel the statistics obtained during the 552 aggregation process, such as standard deviation. In addition to these statistics-based methods, other 553 metrics were used for evaluation such as bias, spatial coverage, number of data points globally and 554 555 representation of features such as biomass burning aerosol plumes, the occurrence of desert dust, or anthropogenic pollution. 556

557 Other validation exercises include studies on uncertainty estimation and studies on the comparison 558 with measurements of aerosol properties at ambient relative humidity (RH) (such as column 559 integrated measurements with associated variations of ambient properties with height) with in situ 560 measurements such as those made in the ground-based networks with controlled RH (cf. Zieger et 561 al., 2011). These exercises were not part of the current RR and will not be reported here.

For the intercomparison of Aerosol-cci data sets, and for the comparison of Aerosol-cci data sets to
other data sets in the ICARE archive (e.g., MODIS, model results, etc.), a multi-sensor visualization

and analysis tool has been developed. All key parameters of each sensor product can be selected 564 independently for visualization. For each product, a link to the product documentation is 565 provided. For a given parameter, a unique colour scale is used for direct visual inter-566 comparison. The geographic selection, date selection, and product selection, can be modified 567 independently, while the other two selection criteria remain unchanged. All data sets are displayed 568 in Plate-Carree projection to make inter-comparison and geographic selection straightforward. 569 Aerosol-cci daily and monthly L3 products don't require any reprojection. Aerosol-cci L2 products 570 are originally produced in sinusoidal grid, so they are re-gridded on-the-fly upon selection in the 571 graphical interface. Additional interactive capabilities are available, such as display of data values, 572 573 or X/Y plot comparison. The multi-sensor visualization and analysis tool is available from http://www.icare.univ-lille1.fr/browse/?project=cci. 574

An extract tool has been developed to interactively extract Aerosol-cci product values in the vicinity 575 576 of validation sites. Several validation networks are supported, including AERONET. Single or multiple parameters from Aerosol-cci aerosol products can be selected for extraction. A time period 577 578 and a search radius can be specified. For each selected validation site, and each overpass of the satellite, all data values found within the specified range are displayed, if any, along with the 579 corresponding acquisition time and pixel location. Those extract values can be directly compared to 580 validation data off-line. The Aerosol-cci extract tool is available from http://www.icare.univ-581 lille1.fr/extract/cci. 582

#### 583 **5.1 L2 statistics**

AOD and Ångström exponent of L2 data sets were compared with AERONET data using scatter plots and least squares fits to the data. The comparisons were made for collocated satellite and AERONET observations, i.e. satellite pixels were selected within a spatial threshold of +/-35 km and a time frame of +/-30 minutes from AERONET measurements. Where available (ORAC, ADV and SYNAER), quality flags or confidence indicators in the products were taken into account to select best pixels. Furthermore a distinction was made between retrievals over land and water.
Round Robin MERIS datasets do not have a water/land flag, therefore the pixels over land and
ocean for MERIS Standard and MERIS BAER were selected using the ORAC water/land flag.

# 592 5.2 L3 scoring

For L3 scoring, an evaluation routine has been developed to determine for a test data set a 593 performance error, for cases when trusted reference data are available. Here the test data are daily 594 L3 satellite data, the reference data are AERONET observations within half an hour of the 595 particular satellite overpass. To simplify comparisons, all sun photometer data were gridded on the 596 spatial 1 ° x1° resolution of the satellite data. Although in theory satellites should locally offer more 597 than 100 samples for the four months, the available number of valid data points is smaller due to the 598 presence of clouds. The number of samples is further reduced due to a limited swath (e.g. AATSR 599 and MISR), stringent quality control measures (e.g. SU) or due to limited temporal coverage (e.g. 600 SYNAER). In addition, also AERONET data were not available each day. 601

The selected performance error for L3 evaluation is based on a combination score, which separately investigates temporal variation, spatial variation and bias. Errors E are defined to range from 0 for 'perfect' to 1 for 'poor'. Conversely, associated scores S (S=1-E) range from 0 for 'poor' to 1 for 'perfect'. This definition for the scores allows via sub-score multiplication the determination of an overall score S<sub>T</sub> and of an overall error  $E_{T}$ .

607

608 
$$\mathbf{E}_{\mathbf{T}} = 1 - |\mathbf{S}_{\mathbf{T}}|$$
 with  $\mathbf{S}_{\mathbf{T}} = \operatorname{sign}(\mathbf{E}_{\mathbf{B}})^* (1 - |\mathbf{E}_{\mathbf{B}}|)^* (1 - \mathbf{E}_{\mathbf{V}})^* (1 - \mathbf{E}_{\mathbf{S}})$ , (2)

609

where  $\mathbf{E}_{\mathbf{B}}$  is the error for bias,  $\mathbf{E}_{\mathbf{V}}$  is the error for spatial variability and  $\mathbf{E}_{\mathbf{S}}$  is the error from temporal or seasonal variability. Note, that the sign of the bias defines the sign of the total score  $\mathbf{S}_{\mathbf{T}}$ . Each of the three sub-scores is based on statistics. Hereby, valid sub-scores require a minimum number of samples. Given sufficient data-pairs for test-data D and reference-data R, the bias score  $\mathbf{E}_{\mathbf{B}}$  compares sums of associated (value-) ranks of an array that contains all elements from both D and R. If the rank sum associated with elements of D ( $D_{SUM}$ ) is similar to the rank sum associated with elements of R ( $R_{SUM}$ ), no bias is determined. However, if the two rank-sums differ, then a bias is identified, in strength and sign.

618

619 
$$\mathbf{E}_{\mathbf{B}} = w^* [(D_{\text{SUM}} - R_{\text{SUM}}) / (D_{\text{SUM}} + R_{\text{SUM}})], w = [I_{Q-R}D + I_{Q-R}R] / [I_{Q-A}D + I_{Q_A}R]$$
(3)

620

Based on the average interquartile range (IQ-R) to interquartile average (IQ-A) ratio of both data-621 sets, a variability factor w is defined. The factor w is applied as weight to the bias error, to avoid an 622 623 error overemphasis, in the case that all individual values are close to their average. The same factor w is also applied to both the spatial variability error  $\mathbf{E}_{\mathbf{V}}$  and the temporal variability error  $\mathbf{E}_{\mathbf{S}}$ . The 624 spatial variability error is based on data-pairs spread spatially at one instance, whereas the temporal 625 626 variability score is based on time-series data-pairs at one specific location. When sufficient datapairs are available, rank correlation tests are performed and the resulting rank correlation coefficient 627 R<sub>C</sub> defines the error. 628

629

630 
$$\mathbf{E}_{\mathbf{V}} = \mathbf{w}^* (1 - \mathbf{R}_{\mathbf{C}})/2$$
 (4)

631 
$$\mathbf{E}_{\mathbf{S}} = \mathbf{w}^* (1 - \mathbf{R}_C /)/2.$$
 (5)

632

With this definition 100% correlation yields no error, whereas 100% anti-correlation yields the maximum error of 1. Note, that randomness for temporal and spatial variability yields still scores of 0.5 (not zero).

Errors of any test data, D, with respect to the reference data set, R, are determined in two parallel steps, at the smallest temporal resolution and at smallest temporal scale. In step 1, temporal error and bias error are determined at each location, by applying available time-series data pairs at the 639 smallest temporal resolution. In step 2, spatial error and bias error are determined by exploring data 640 pairs in their spatial context for each time step. The final bias error is averaged from both 641 processing steps.

Since properties usually vary with longitude / latitude and surface conditions, the evaluation is regionally stratified. Later these regional scores can be easily combined via average weighting into a single global score. Thus, this method offers an assessment via a single global (or regional) score, while still maintaining regional diagnostics on bias the ability to match temporal and spatial variability.

#### **5.3 Level3 validation using AEROCOM methods**

The L3 validation of daily gridded products using AEROCOM tools is applied to the nearest satellite pixel value on a 1° x 1° grid corresponding to daily mean AERONET values excluding mountain sites. The evaluation with the AEROCOM tools provides bias, histograms, scatter plots, time series graphs, zonal mean comparisons, and score tables. This analysis includes all pixels regardless of quality flags or confidence indicators. A specific focus was put into common data point filters between the AATSR algorithms. The ORAC land / sea mask was used for all retrievals to differentiate between land, coast and sea cases.

## 655 6. Round Robin exercise

656 The Round Robin exercise was set up for an independent and objective evaluation of the global retrieval results (AOD, AE) provided by each of the algorithms indicated in Section 3. The versions 657 of the algorithms used to provide these products were selected by each of the retrieval groups based 658 on the exercises described in Holzer-Popp et al. (2013) and summarized in Section 4. The results 659 were evaluated using the tools described in Section 5. Based on these results, the independent 660 validation team (Section 2) provided an advice as regards the statistical quality. Other 661 considerations were data coverage and spatial patterns. In addition, the same tools (Section 5) were 662 applied to data from MODIS Aqua, MODIS Terra and MISR, for intercomparison and as a measure 663

of how well the Aerosol-cci algorithms are performing in comparison to other satellite data setswhich are often used in climate studies.

- For an objective evaluation of the RR results, a protocol was developed using the following rules:
- evaluation was performed by independent Aerosol-cci partners, i.e. partners not directly
   involved in providing retrieval data: the validation team (Section 2);
- A set of criteria for selecting the best algorithm was developed beforehand:
- o using the statistics (L2), ranking based on scoring (L3), and L3 validation using
  AEROCOM tools, as described in Section 5
- o evaluation of performance on global and regional scales
- 673 o evaluation of seasonal performance
- evaluation of spatial coverage, reproduction of regional and global patterns and the
   occurrence of features such as desert dust and biomass burning plumes,
   anthropogenic pollution, etc.
- 677 Additional considerations for algorithm selection were:
- long-term application potential (follow-up or predecessor sensors)
- availability / quality of uncertainty information on pixel level
- ability to provide essential complementary data to available satellite data products
- technical criteria such as the operationality of algorithms (e.g., throughput, dependence to
   systematic external datasets, implementation efforts).
- The rankings provided by the validation team, i.e. based on statistical results, are presented in Table3 and discussed below.

# 685 6.1 Level2 validation

For the L2 evaluation of AOD and AE provided by the participating algorithms statistical measures
evaluated were Pearson correlation coefficients, linear fit parameters, standard deviations (from
linear fits and from AOD difference histograms), average differences, and number of AERONET

689 sites and satellite pixels used. Examples of scatterplots between the satellite-retrieved AOD and AE 690 vs. AERONET data are shown in Figures 1 and 2, together with the fit parameters. These figures illustrate that there are differences amongst the several AATSR algorithms, both over ocean and 691 over land, and between the AATSR and PARASOL results over ocean. In all cases over ocean 692 satellite AOD is reasonably well correlated with AERONET, although outlyers are observed for 693 ORAC, which may be due to insufficient cloud screening. Over land SU AOD is well correlated 694 695 with AERONET and the slope is close to 1, but for ADV and ORAC the correlation is less good 696 than over ocean.

697 Figure 1 about here

698 Figure 2 about here

699 Correlations of AE are much smaller than for AOD, especially over land where in most cases there 700 is no correlation. Over ocean the correlations are much better and the PARASOL AE seems to 701 follow AERONET values reasonably well. It is not clear why the SU results are not at all correlated 702 with AERONET over ocean and AE's are mostly very close to zero.

703 Criteria used for ranking of the L2 validation results are based on correlation coefficient, standard
704 deviation and number of satellite pixels using the following criteria:

- The closer the linear Pearson correlation coefficient is to 1, the better the algorithm (both for
   AOD(550 nm) and AE).
- The smaller the standard deviation of the difference between retrieved and AERONET
   AOD, the better the algorithm (both for AOD(550 nm) and AE).
- Algorithm should provide enough number of the retrieved pixels.

The application of the criteria leads to the following rankings for the algorithms using AATSR orMERIS data (see also Table 3):

712 AATSR over ocean: ADV, ORAC, SU, SYNAER

713 AATSR over land: SU, ADV, ORAC, SYNAER

#### 714 MERIS over ocean: ALAMO, ESA standard

It is noted that BAER was not included because no products were available at the time the RR was conducted. This ranking is based on the statistics provided in Table 4. These statistics show that from all participating algorithms, over ocean PARASOL shows the best combination of high correlation, small standard deviation and large pixel number, but also AATSR ADV and MERIS-ALAMO have good correlations. Over land AATSR SU shows good correlations, whereas MERIS has clearly weaker correlations and larger standard deviations, with only slightly larger pixel numbers.

#### 722 **6.2 L3 scoring**

The evaluation of L3 data as described in section 5.2 was separately conducted for 25 (TransCom; Gurney, et al. 2002) sub-regions shown in Figure 3. Within each of these 25 regions, at least 10 data-pairs were required for both the spatial and the temporal test in order to get a valid score. This required sufficient satellite data samples and also sufficient  $1^{\circ}x1^{\circ}$  grid boxes in each region with AERONET coverage.

728 Figure 3 about here

These data-pair requirements permitted only scores for the Northern Hemispheric land regions with sufficient AERONET coverage. Unfortunately, also for these regions collocated satellite and AERONET data were often so sparse that a valid score was not possible. Table 5 shows the resulting satellite AOD retrievals scores.

Table 5 about here

Table 5 indicates that the data volume of the Aerosol-cci AOD retrievals for the test period (four months in 2008) which matched to AERONET data is so sparse that no scores can be offered. Even those Aerosol-cci AOD products which allow scoring have much poorer coverage than MODIS and even MISR (which has an even smaller swath of about 360km compared to about 500km for

AATSR). This is also illustrated by the number of samples that contribute to the scores for NorthAmerica, where also sub-scores for bias, temporal variability and spatial variability are listed.

Among the different Aerosol-cci AOD retrievals the ATSR products show the highest skill but total and sub-scores vary. However, the comparison of the scores is limited. Global scores are based on different numbers of regions. And also more appropriate comparisons for North America, where almost all products supply a score, the underlying numbers of data-pairs differ.

For North America, ADV is ranked before SU and ORAC. The ADV score (.54) matches the MISR score and both the ADV, MISR and SU (.48) scores are better than the MODIS scores (.42/.41) which are particularly poor over America. Looking at the sub-scores, the relatively low ORAC score (.39) has a bias score that is as good as in MISR or MODIS and clearly better than for SU. The sub-scores also indicate that ADV and SU display spatial distributions for North America which are superior among the examined data sets, even better than MISR or MODIS.

Calculated regional errors, as well as contributing sub-errors due to spatial variability among
 MODIS, MISR and ADV are compared in Figure 4. The same error comparisons among the three
 ATSR products are presented in Figure 5.

753 Figure 4 about here

Figure 5 about here

Figure 4 indicates that ADV errors for North America and Europe (where a sufficient amount of AATSR data are available) are as low as for MISR (v22) and better than for MODIS (Collection 5.1). However, as mentioned above, the data volume of MISR and ADV is much smaller than that offered by MODIS, mainly due to their narrower swaths. It is further noted that the ADV data volume is similar to that of the MISR data, despite the larger AATSR swath. In that sense it should be noted that the value of satellite products is not only determined by its accuracy alone but also by (frequent, global) coverage.
The comparison of the three AATSR algorithms shows that the data coverage is poor for the SU product. Clearly efforts are needed for better coverage to make these data sets more attractive to users. For regions with available scores it could be concluded that the ADV product scores best and that the ORAC product scores poorest, despite having a relatively low bias error. Still, this is just based on an analysis for two regions dominated by urban-industrial aerosol and there are much more facets to aerosol (e.g. dominance by dust or biomass burning).

Clearly these initial comparisons leave many open questions. Most disturbing is that there are so many regions where no scores could be calculated for this limited data set. This can be addressed once data are provided for one entire year or more. Also reference data over oceans are needed and will be added in future assessments (e.g. using data from the marine aerosol network (Smirnov et al., 2012) or using trusted and matured satellite AOD products).

#### 773 **6.3 Level3 validation using AEROCOM tools**

The AeroCom tools allow for the selection of regions (World, Europe, China, India, E. Asia, N 774 775 Africa, N. America, S. America, World w/o mountains) and annual (only a four month average for 2008 in this RR), seasonal (represented by 4 different months), and monthly L3 (4 months in 2008) 776 averages. A common 1°x1° mask was established where valid data were available from all retrieval 777 778 algorithms (AATSR and MERIS). In all regions this info is further refined using an ocean, coastal and land mask, based on whether a grid point was identified as purely ocean or land across 779 retrievals (using the ORAC L2 land/sea mask). Remaining grid points are defined as coastal. 780 Altogether 8 x 4 regional selections are possible. For comparison, similar statistics are available for 781 782 the annual averages of MODIS-Terra, MODIS-Aqua and MISR AOD data, with selection by 783 region. For each selection a list is produced showing the statistics, cf. Figure 6 as an example. Examples of the results are presented in Figures 7 - 12. 784

Fiigure 6 about here

Figure 7 shows the global annual mean AOD maps for the algorithms participating in the Aerosol-786 787 cci RR, as well as reference AOD maps from MODIS v5.1 (Terra and Aqua), MISR and the AEROCOM median. As compared with the baseline algorithms (Holzer-Popp et al., 2013), the 788 current results are much closer to each other and also closer to the references. Yet, also quite large 789 differences are observed, both as regards the global coverage, the number of valid pixels (provided 790 with the statistics given with Figure 9), the spatial distributions and the features in each of the maps. 791 Clearly, ADV provides the smallest global coverage, which is also reflected in the number of valid 792 pixels which is smaller than for ORAC and MERIS Standard, but larger than for SU. The small 793 number of ADV pixels is due to the facts that (a) ADV limits the retrieval to solar zenith angles of 794 65° and (b) no retrieval is made over bright surfaces. The even smaller number of pixels provided 795 by SU, in spite of the larger global coverage, is due to a stricter quality control. Further, there are 796 clear differences in the global mean AOD (provided for each algorithm in the legend at the top at 797 798 the right), which vary from 0.154 for ADV to 0.215 for SYNAER, as compared to MODIS mean AOD values of 0.189 (Terra) and 0.179 (Aqua) and MISR (0.176). 799

800 Over land there are clear differences in the AOD distributions, such as at high northern latitudes where the AOD provided by ORAC and MERIS Standard are clearly higher, SYNAER is a bit 801 higher, and ADV provides distributions similar to those from the reference satellites. SU, on the 802 other hand, provides AODs which are substantially lower. It is noted that the AEROCOM median 803 shows somewhat lower AODs at northern latitudes, with a clear gradient over Siberia, than the 804 reference satellites. Over western Europe, most AOD maps show enhanced values, higher than 805 further north, except ORAC and MERIS Standard, while the reference satellites show no 806 807 enhancement over western Europe with respect to northern latitudes, in contrast to the AEROCOM median. Over N. America the patterns are quite different between different satellites (both Aerosol-808 cci and references). The AOD is lower in the west for ADV, ORAC and SU, but there are clear 809 differences between these algorithms as regards the patters, and the values for ORAC are higher all 810

over the continent. The lower AOD in the western USA is in agreement with AEROCOM median. 811 812 In contrast, the AOD in the west is higher than in the eastern USA for SYNAER and MERIS Standard, and this is also observed, although less clear, for MODIS, while MISR shows no clear 813 differences across the USA. It is noted that differences between MODIS and MISR AOD 814 observations have been reported; e.g. van Donkelaar et al. (2010) noted that over the SW USA a 815 large AOD enhancement was observed in the MODIS retrievals but not from MISR. Also over S. 816 America there are large differences with a very high AOD over the northern part from ORAC and 817 an overall high AOD from SYNAER and MERIS Standard. SU shows the largest spatial variations 818 and ADV and the reference satellites are quite close in their AOD values with little or no gradients 819 820 (on the scale on which AOD is displayed). Similar comments can be made over Africa, where all retrievals clearly show the biomass burning plumes, but with different intensity. Also there are clear 821 indications of the Sahara desert dust plumes but the analysis of differences between algorithms is 822 823 difficult because several algorithms do not provide data over bright surfaces, such as the Sahara.

Over ocean there are also considerable differences. ORAC provides a clear pattern with very low 824 825 AODs over most of the southern oceans and a transition across the tropics to the northern hemisphere. The low AOD values over ocean are in line with values reported by Smirnov et al. 826 (2012) based on hand-held sun photometer observations on ships of opportunity as reported in the 827 Marine Aerosol Network (MAN). Unfortunately the MAN observations for 2008 were too sparse to 828 be used in the Aerosol-cci RR validation. Low AOD values, but much less prominent, over the 829 southern oceans are also observed in the SYNAER and MERIS ALAMO AOD maps, and in the 830 southern Pacific in the AEROCOM median. Also MODIS Aqua, MERIS Standard and ADV 831 indicate low AOD in the southern Pacific. AEROCOM further shows a clear band with enhanced 832 AOD in the southern hemisphere between roughly  $40^{\circ}$  and  $60^{\circ}$ , which is reproduced to some extent 833 by ORAC, somewhat less clear by ALAMO and weakly by the reference satellites. 834

The overall picture emerging from these maps is that the ADV AOD distribution is closest to that of 835 836 the reference satellites, both over land and ocean, but ADV does not provide any data at the higher latitudes resulting in a the global coverage which is much less (ca. 30%) than for some other 837 Aerosol-cci algorithms. The global mean AOD produced by most algorithms is different but locally 838 the differences are much larger, and these local differences are to some extent cancelled in the 839 global mean. Therefore it is useful to also look at regional differences to learn the strengths and 840 weaknesses of each algorithm and thus improve the algorithms. Features over land, such as forest 841 fire, desert dust and anthropogenic pollution plumes usually are smoothly extended over ocean but 842 in many cases land-sea transitions are visible. This is clearly a point for future research. 843

844 Figure 7 about here

Monthly AOD maps, for one month in each season selected for this RR exercise, are presented for 845 ADV and PARASOL in Figure 8. The features are similar as those discussed in Figure 7, but there 846 847 are clear differences between seasons in relation to the production and removal of different aerosol types. This is most clearly illustrated with the biomass and desert dust plumes generated over Africa 848 and transported over the Atlantic Ocean. There are also clear differences in the AOD distributions 849 over the continents such as over Asia (China, India, deserts) and adjacent downwind oceans. 850 Differences are also visible over N. America (features discussed in connection with Figure 7) and 851 852 over S. America which is likely connected with biomass burning in Amazonia. In addition there are differences between coverage caused by the seasonal variation of the solar zenith angle. 853

Fiigure 8 about here

Examples of the AEROCOM statistical analysis of the Aerosol-cci results for the 4 months in 2008 are presented in Figures 9, 10 and 11. Figures 9 and 11 include MODIS Terra evaluation results as a reference. MODIS Terra was selected here because the overpass time is close to that of ENVISAT with AATSR and MERIS. Figure 9 shows scatterplots of the retrieved AOD vs. AERONET values. The statistics are provided in the legend in the upper left corner of each plot. The algorithm name is

given along the vertical axis of each plot. The scatterplots illustrate the differences between the 860 861 various algorithms and how much they deviate from the reference value. These differences are quantified, in a statistical sense, by the correlation coefficient, the bias and the rms. Figure 9 shows 862 scatterplots including data for all 4 months considered in Aerosol-cci for the whole globe, i.e. 863 including land, ocean and coastal regions, whereas the bar charts in Figure 10 differentiate between 864 land and coastal for each month separately; there are not enough L3 collocations over ocean to 865 provide meaningful statistics. The data shown in Figure 10 have been used to provide a ranking 866 between the four AATSR algorithms, Table 6. The numbers in Table 6 are the number of months, 867 out of a total of 4, when a certain algorithm performed best, 2nd best etc. based on two statistical 868 869 parameters: correlation and RMS. The results show that over land ADV provides the best results, before SU, and in coastal areas SU ranks before ADV. ORAC is sometimes close. 870

These numbers can therefore be used to provide a ranking, however, the statistics also provide a quantitative number, in a statistical sense, showing how large (or small) the differences between the algorithms are, which has been used to provide the ranking presented below.

Fiigure 9 about here

Fiigure 10 about here

Table 6 about here

Figure 11 shows the statistics in a different way, as histograms of the frequency of occurrence of the 877 AOD values retrieved form the satellite observations, compared with collocated AERONET 878 observations. Ideally, the two curves should exactly coincide. However, even MODIS, with 1468 879 collocations (note that these data are available for the whole year 2008, i.e. no selection was made 880 to cover only the 4 months used for the RR algorithms, or to select on collocations with Aerosol-cci 881 satellite data) does not provide an exact coincidence and the lower AODs are on average somewhat 882 overestimated whereas the higher AODs (around 0.2) are somewhat underestimated by MODIS. For 883 the Aerosol-cci algorithms, covering only 4 months and thus having much less collocations, the 884

histograms show larger variations between bins. Yet, ALAMO and PARASOL, with over-ocean 885 retrieval only, follow the AERONET pattern quite well, with a tendency for PARASOL to 886 underestimate the lowest AODs. It is noted here that only AERONET data (i.e. land based) were 887 used in this analysis, i.e. sun photometers situated at or near the coasts, which may result in some 888 bias. From the other algorithms, the ADV-retrieved AOD histogram follows that of AERONET 889 quite well; this can also be said from SYNAER although the histograms are very flat. In the other 890 891 algorithms deviations are visible with either overestimation of the lower AOD values (SU) or underestimation (ORAC) whereas MERIS Standard appears to have the largest deviations for both 892 small and large AOD. 893

Fiigure 11 about here

Another way to use the statistics is to evaluate where algorithms perform well and where 895 improvements are needed. An example is presented in Figure 12 where the difference between the 896 897 satellite and AERONET AOD observations, given by (Satellite -AERONET)/AERONET\*100, is colour-coded on the map for individual AERONET stations across the world. Blue indicates that the 898 899 satellite is underestimating; red indicates that the satellite is overestimating. Light colours indicate that the differences are very small and as the colour is darker the under of over-estimation is larger. 900 For these plots, the globe has been gridded into boxes of 10°x10°. For each grid box, the stations 901 902 located there are taken into account, and their data is then averaged depending on the time period to be plotted. When smaller regions are considered instead of the whole globe, the grid is reduced to a 903 1°x1° grid. The plot does not show how many stations are within the grid box. The locations of the 904 grid boxes (especially at the plot for the whole globe) are not entirely correct, because while the 905 906 outline of the continents and countries are correct according to the map projection, the grid boxes are not. This would require a reverse map projection which would destroy the analysis grid because 907 of associated interpolations. The error becomes greater as the boxes are further away from the 908 equator and the zero meridian. 909

The maps show that none of the algorithms, including the MODIS reference, is perfect everywhere. 910 911 Improvements are needed, but areas for which the improvements are needed, and in which direction (under- or over-estimation), are different for each algorithm. Taking the AATSR algorithms as an 912 example, ADV and SU appear to perform reasonably well over Europe, even though they tend to 913 underestimate, whereas ORAC and SYNAER have large overestimation. The same pattern emerges 914 over the USA, except that SYNAER appears to work quite well over the eastern USA. Almost all 915 algorithms show a large overestimation at high latitudes, except ALAMO in the northern 916 hemisphere. Because AERONET stations are located over land, or in coastal areas, this evaluation 917 cannot be made over ocean. 918

919 Figure 12 about here

Figure 13 shows the zonal mean AOD for the Aerosol-cci algorithms and MODIS Terra, with 920 AERONET for comparison. Together with Figure 11, this figure illustrates the performance of each 921 922 algorithm. As in Figure 11, ideally the satellite-retrieved AOD would follow the AERONET observations, as for MODIS Terra in Figure 13. Also the over-ocean only AODs provided by 923 924 ALAMO and PARASOL show a quite good behaviour. However, for the other algorithms, which include both land and ocean in the plots in Figure 13, the trends are reproduced well with high AOD 925 north of the equator and lower AODs toward the poles, but quantitatively there are differences. 926 MERIS Standard is in the (sub-) tropics very close to AERONET, but at mid-latitudes the AODs 927 are much higher than those from AERONET. Similar observations can be made for SYNAER, but 928 the SYNAER AOD shows an increasing trend from south to north as opposed to all other 929 observations. From the other AATSR algorithms, ADV deviates quantitatively most from 930 931 AERONET, whereas ORAC follows AERONET quite well but peaks right at the equator and has much higher values both at  $-60^{\circ}$  and in the far north. SU seems to give the best performance in this 932 comparison except for the very high values in the far north. 933

The overall ranking resulting from the evaluation with the AEROCOM tools is given in Table 3.

Figure 13 about here

### 936 **7. Discussion**

The combined effort of European aerosol retrieval teams, supported by MODIS and MISR retrieval 937 specialists participating in workshops and discussion meetings, has resulted in an enormous 938 improvement of the retrieval algorithms and the products resulting from them. These efforts have 939 940 been described in Holzer-Popp et al. (2013) and were briefly summarized in Section 4 of this paper which is focused on further improvement and algorithm inter-comparison with the goal to use the 941 algorithms for climate studies. This application requires a very high accuracy as formulated by 942 943 climate users, and the inclusion of uncertainties per pixel. To evaluate algorithm performance, as judged by the evaluation of their products, in this case mainly the AOD and to a lesser extend the 944 wavelength dependence of the AOD expressed by the AE, methods have been developed as 945 described in section 5. The results from the application of these algorithms are presented in Section 946 6. The evaluation of these results shows, in a quantitative way, based on results from statistical 947 methods and additional evaluation using subjective but informed methods based on existing 948 knowledge of how aerosol varies on regional and global scales, the good performance of the 949 950 PARASOL (v0.23a) and the MERIS ALAMO (v1.0) algorithms over ocean, and the improvement of the AATSR ADV, SU and ORAC algorithms for use over both land and ocean. The other 951 algorithms, SYNAER and MERIS Standard, need further improvement before they can be used to 952 provide parameters useful for climate studies. MERIS BAER needs further improvement with 953 respect to cloud screening and the consideration of absorbing aerosols. This situation led to the 954 conclusion that, in view of their good performance, the PARASOL and the MERIS ALAMO 955 algorithms can be used for the retrieval of AOD over ocean and thus provide 10 years (MERIS) and 956 7 years and more (PARASOL) global data series. 957

958 For AATSR, all three algorithms using only AATSR data (ADV, ORAC, SU) show good 959 performance, although there are regional and seasonal differences. However, there is not one

algorithm which performs best everywhere, as shown by the rankings provided in Section 6 from 960 961 each of the three different methods. Overall, ADV appears to provide the best scores, and compares most favourably with the reference satellite data sets, but it does not provide any retrieval over 962 highly reflecting surfaces. SU does provide retrievals over highly reflecting surfaces but the number 963 of data points is very small, mainly due to the application of stricter quality control than ORAC and 964 ADV. However, this stricter quality control does not lead to the highest scores everywhere. ORAC 965 is potentially the most consistent algorithm in a mathematical sense, however both statistically and 966 as regards the reproduction of features it performs less well than ADV and SU. Yet, the low AOD 967 over ocean seems to be in line with results published by Smirnov et al. (2012). Nevertheless, ORAC 968 does not rank highest over ocean, which may be due to the lack of independent validation data over 969 open ocean which could confirm the low AOD observed by ORAC. Based on the current RR 970 results, ADV ranks first, followed by SU with ORAC as third. Yet, the differences are so small, that 971 972 the ranking may change when further improvements are implemented. Furthermore, the ranking may be influenced by uncertainties introduced by L3 sampling methods as discussed in Sayer et al. 973 974 (2010).

Much of the difference between algorithms and their scoring may be due to cloud masking. The different cloud masks used by each of the algorithms slightly complicates the like for like comparison especially as common filtering may not completely account for possible differences in cloud masks or thresholds used at the  $10x10 \text{ km}^2$  retrieval level. As pointed out in the introduction, the comparison with AERONET data, which are well screened for cloud occurrence, does not provide a good test for how well clouds have been detected in satellite data and the results may be influenced by the occurrence of residual clouds.

982 Several recommendations resulted from the RR exercise. One of them was that, although the ADV 983 algorithm overall ranking was best, the coverage was a problem and needed to be improved. Such 984 improvement could be found from increasing the maximum solar zenith angle used in the retrieval

from 60 to 75 degrees which would give a similar coverage as other algorithms and from the 985 986 implementation of a module to model the reflectance of bright surfaces such as applied by SU. The latter has been implemented in ORAC V2, together with the ADV post-processing step and initial 987 results are better than those described here. SU in turn has increased the number of pixels retrieved 988 by using a less strict quality control together with the ADV post-processing. The implementation of 989 these changes requires thorough testing and evaluation of the results to avoid loss of accuracy and 990 991 production of erroneous results. Hence such improvements will be reported in subsequent papers. Thus a similar round robin exercise should be repeated with improved algorithms and the current 992 conclusions should be regarded as a snapshot evaluation of continuous algorithm development. 993

### 994 **8. Conclusions**

A validation protocol and necessary tools to implement the protocol have been developed and were 995 applied to 7 algorithms for aerosol retrieval using AATSR (4, one synergistic with SCIAMACHY), 996 MERIS (2) and PARASOL data. For reference, these tools were also applied to MODIS and MISR 997 data. The application of these tools, to L2 and to L3 data using different statistical methods and 998 scoring based on a combination of methods, revealed the strengths and weaknesses of each 999 1000 algorithm as well as a scoring of both the Aerosol-cci and the reference algorithms. A crucial issue 1001 is the dependence of validation scores on data filtering – this led to the development of a common point filter to assure the comparison of equivalent datasets. 1002

The results show that PARASOL has the highest accuracy over ocean and covers features well. The AATSR algorithm ranking depends critical on filtering. Overall (features, validation) ADV and SU seem better than ORAC which provides some unrealistic high features. SU and ADV scores are similar over land with SU providing data over bright surfaces and ADV having a better coverage of features. Over ocean ADV seems best (except coasts). A combination ADV generally + SU over bright surfaces + coasts could provide best products. MERIS ALAMO performs well over ocean; MERIS standard has large overestimations of AOD over land. SYNAER overestimates the AOD, has lower coverage and accuracy but a rather good coverage of features (except in central Asia andhigh latitudes).

The scoring method shows that the AATSR algorithm results are close to or somewhat better than 1012 1013 those from MODIS (and close or similar to MISR), but the number of points retrieved is much smaller than MODIS due to swath width and the availability of only one instrument as opposed to 1014 two MODIS instruments. Obviously, this gap cannot be closed. However, the dual view provided 1015 1016 by AATSR makes this instrument potentially better suited for aerosol retrieval over land. Also, it provides one of the longer time series with the combination of ATSR-2 and AATSR (1995-April 1017 2012), with an extension by SLSTR (Sea and Land Surface Temperature Radiometer) planned to be 1018 1019 launched in April 2014 as part of Sentinel-3. Sentinel-3 also has OLCI (Ocean Land Colour Instrument), which will extend the 10 years of MERIS observations. 1020

Taking into account the results from the RR exercise, the improved algorithms will be used to provide a 1-year data set (2008) of Aerosol ECV products which, after validation using similar tools as described in this paper, will be offered to the climate modelling community for their validation and feedback as regards the use for climate studies. Taking these into account, the full 17 years of ATSR-2 / AATSR is planned to be processed.

A round robin exercise for aerosol ECVs cannot be conducted using a fully automatic scoring since trade-offs between coverage and accuracy or between added value and accuracy need to be made. This requires scientific expertise and a team dialogue to come up with conclusions which meet the standards of peer review by the scientific community. A strong user involvement in the whole validation and selection process is crucial to understand and take into account the user needs.

1031 The cooperation of the EO community with the global modelling community has proven to be very 1032 important, in particular as regards the production of a data set in such a way that they are indeed 1033 useful for climate studies. The cooperation between the EO groups, which was the first time on a

European level, has led to large improvement of almost all retrieval products. The initial gap with non-European products (in particular MODIS) has become much smaller.

#### 1036 Acknowledgements

The results presented in this paper were achieved within the Aerosol cci project funded by the 1037 European Space Agency (ESA) as part of the ESA Climate Change Initiative (CCI). We 1038 1039 acknowledge AERONET in situ aerosol data providers through which ground based measurements for the validation activities in the project were acquired, as well as ICARE and AEROCOM which 1040 played a crucial role in the data validation and data storage services. Aerosol retrieval work by 1041 1042 sevral participants is supported by a range of other ESA projects than the Aerosol-Climate Change Initiative as well as EU FP6 and FP7 grants. ALAMO has been developed by HYGEOS and LOA 1043 with the collaboration of ICARE and with partial financial support of CNES " Centre National 1044 d'Etudes Spatiales" 1045

		nr of pixels	221	285	99	61	262	103	384

1317 AE(555-865)

\*For ADV, AE(555-1610) yields similar statistics (cc=0.66, st dev= 0.37, bias=0.05), but the
average AE is lower.

Table 5. Comparison of scores (1-error) for different AOD satellite retrievals for year 2008 data of 1321 the months March, July, September and December. The larger the absolute value of the score, the 1322 better the performance, with the overall sign indicating the bias vs. AERONET. The left side 1323 1324 presents scores for the globe, land and oceans. The right side presents total and sub-scores for North America. The global scores are difficult to compare as the number of contributing regions differs, 1325 thus there is a focus for North America, where most data provide a score. Note that the total number 1326 of areas for which a score would be possible is 25 (Figure 3). Also note that even for North America 1327 the number of data pairs varies strongly and is for some Aerosol cci data so small that no score can 1328 be provided (regions contributing given in columns "areas" for global and "data pairs" for North 1329 1330 America). For North America the scores are broken down to the sub scores for bias, temporal correlation and spatial correlation. No scores are given for SYNAER, ALAMO and ESA Standard 1331 because the number of samples was too small. 1332

	10+ samples	global scores			-	North A	merican	scores	5	
		ocean	ocean	Land	nr. of	total	Bias	Tem	Spa	nr of
		& land			areas			poral	tial	pairs

SU	2	1	1	0				
ORAC	1	1	2	0				
SYNAER	0	0	0	4				

1336 of collocations is too small to provide meaningful scores.

1337

## 1339 Figures

Figure 1. Examples of scatterplots between the satellite-retrieved AOD and AE vs. AERONET data. AOD over ocean (top row) and land (bottom row) were separated using the ORAC land/sea flag for all retrievals. The algorithm is indicated along the vertical axis. Statistics from a least squares fit of the type y=ax+b are indicated in the legends at the bottom (see also Table 4): K is the correlation coefficient, a is the slope, b is the bias and St.D. is the standard deviation.

Figure 2. Examples of scatterplots for Ångström exponents vs. AERONET data, for furtherexplanation see Figure 1.

1352 Figure 3. Regional stratification of the globe following TransCom (Gurney, et al. 2002).

Figure 4. Regional error comparisons between MODIS (left), MISR(center) and ADV (right). Errors are only displayed for regions with sufficient data-pairs to co-incident AERONET sunphotometer samples. Aside from total regional average errors (top row), also contributing regional sub-errors for spatial variability and bias are presented.

1354

Figure 5. Regional error comparisons between AATSR algorithms ADV (left), SU (center) and ORAC (right). Errors are only displayed for regions with sufficient data-pairs to co-incident AERONET sun-photometer samples. Aside from total regional average errors (top row), also contributing regional sub-errors for spatial variability and bias are presented.

- 1371 Figure 6. Satistics from the L3 AEROCOM validation for the World Annual Average (4 months in 2008)
- 1372 AATSR ADV.v1.3-Set3D AOD data.

Figure 7. Global annual mean AOD maps for all algorithms participating in Aerosol-cci as well as
reference maps. Top: AATSR ADV, ORAC, SU, SYNAER; Middle: MERIS Standard, ALAMO,
PARASOL; Bottom, MODIS Terra, MODIS Aqua; MISR, AEROCOM median. Note that ALAMO
and PARASOL are only used over ocean.

1381 Figure 8. Global AOD maps of the AOD retrieved using ADV for AATSR data (top row) and for

1382 PARASOL data (bottom row) for the months March, June, September and December (left to right),

selected in this RR exercise to cover one month in each season.

1386

identified on the vertical axis of each figure plotted on a log-log scale versus AERONET AOD. The

lines indicate the 1:1 and the factor 2 limits. Results from a least squares fit are provided in the

1390 legend at the upper left corner of each figure.

1393Figure 10. Bar charts showing the seasonal variation (as given by 1 month in each season) of the

1394 correlation coefficient and RMS over land and in coastal regions for the 4 algorithms using AATSR

1395 data. Over ocean there are too few collocations to provide meaningful statistics for each month.

1396

1398

1399

Figure 11. Histograms showing the frequency of occurrence of the AOD values provided by each Aerosol-cci RR algorithm and MODIS Terra (in red), together with that of the AERONET reference values (in blue), together with the global mean value and the percentage of points with an AOD of greater than 0.6 which are not shown in the plot (indicated as "outside"). The number of collocations is given in the top left legend, top line, the algorithm is indicated in the second line.

1405

Figure 12. Evaluation of the performance of the Aerosol-cci algorithms and, for comparison,
MODIS Terra. The plots show the difference between the satellite-derived AOD and the
AERONET AOD, as explained in the text, the colour scales are given to the right of each map.

1414 Figure 13. Zonal mean AOD for the 4 months in 2008 for the Aerosol-cci algorithms and MODIS

1415 Terra (all in blue) and AERONET (in red).
