Abstract. Pollutant plumes with enhanced concentrations of trace gases and aerosols were observed over the southern coast of West Africa during August 2006 as part of the AMMA wet season field campaign. Plumes were observed both in the mid and upper troposphere. In this study we examined the origin of these pollutant plumes, and their potential to photochemically produce ozone (O₃) downwind over the Atlantic Ocean. Their possible contribution to the Atlantic O₃ maximum is also discussed. Runs using the BOLAM mesoscale model including biomass burning carbon monoxide (CO) tracers were used to confirm an origin from central African biomass burning fires. The plumes measured in the mid troposphere (MT) had significantly higher pollutant concentrations over West Africa compared to the upper tropospheric (UT) plume. The mesoscale model

reproduces these differences and the two different pathways for the plumes at different altitudes: transport to the north-east of the fire region, moist convective uplift and transport to West Africa for the upper tropospheric plume versus north-west transport over the Gulf of Guinea for the mid-tropospheric plume. Lower concentrations in the upper troposphere are mainly due to enhanced mixing during upward transport. Model simulations suggest that MT and UT plumes are 16 and 14 days old respectively when measured over West Africa. The ratio of tracer concentrations at 600 hPa and 250 hPa was estimated for 14–15 August in the region of the observed plumes and compares well with the same ratio derived from observed carbon dioxide (CO₂) enhancements in both plumes. It is estimated that, for the period 1–15 August, the ratio of Biomass Burning (BB) tracer concentration transported in the UT to the ones transported in the MT is 0.6 over West Africa and the equatorial South Atlantic.

Runs using a photochemical trajectory model, CiTTY-CAT, initialized with the observations, were used to estimate in-situ net photochemical O₃ production rates in these plumes during transport downwind of West Africa. The mid-troposphere plume spreads over altitude between 1.5 and 6 km over the Atlantic Ocean. Even though the plume was old, it was still very photochemically active (mean net O₃ production rates over 10 days of 2.6 ppbv/day and up to 7 ppbv/day during the first days) above 3 km especially during the first few days of transport westward. It is also shown that the impact of high aerosol loads in the MT plume on photolysis rates serves to delay the peak in modelled O₃ concentrations. These results suggest that a significant fraction of enhanced O₃ in mid-troposphere over the Atlantic comes from BB sources during the summer monsoon period. According to simulated occurrence of such transport, BB may be the main source for O₃ enhancement in the equatorial south Atlantic MT, at least in August 2006. The upper tropospheric plume was also still photochemically active, although mean net O₃ production rates were slower (1.3 ppbv/day). The results suggest that, whilst the transport of BB pollutants to the UT is variable (as shown by the mesoscale model simulations), pollution from biomass burning can make an important contribution to additional photochemical production of O₃ in addition to other important sources such as nitrogen oxides (NO_x) from lightning.

1 Introduction

Biomass burning produces large quantities of pollutants which can be transported many thousands of kilometres downwind. This includes trace gases such as CO₂, and precursors of O₃ as well as aerosols which can also have an important impact on radiative forcing. Production of O₃ downwind from source regions also influences the global oxidizing capacity through the formation of the OH radical, and thus the lifetime of greenhouse gases such as methane. Africa is the continent emitting the largest quantity of biomass burning (BB) emissions with a strong inter-hemispheric transition between West Africa in boreal winter to central and southern Africa in boreal summer (Crutzen and Andreae, 1990) following the location of the dry season in each hemisphere. O₃ production in African fires has been studied by Mauzerall et al. (1998). Using a box model they analysed measurements taken during several days over South and central Africa in a BB plume. They found that O₃ was produced in the BB plume only during the first 3 days after emission, followed by net O₃ destruction. They also found that due to plume dilution, O₃ concentrations in the plumes increased only during the first 24 h. Chatfield et al. (1996) also simulated O₃ production in BB plumes transported over the South Atlantic and estimated a slow 0.5–1 ppbv/day decrease in O₃. In contrast, Thompson et al. (1996a) in a study based on measurements

taken over continent but also over the Atlantic estimated O₃ production rates over the Atlantic of 1–4 ppbv/day attributed to BB plumes. Jacob et al. (1996) also estimated the O₃ budget over the Atlantic based on Atlantic measurements and found slow net O₃ production above 4 km. Therefore, previous BB simulations studies (not based on measurements or based on measurements close to the emission) seem to fail to reproduce positive O₃ production observed in BB plumes over the Atlantic, far from source emissions.

One important feature of African tropospheric O₃ is the so-called maximum O₃ pattern (Weller et al., 1996; Thompson et al., 1996b; Jenkins and Ryu, 2004a): high concentrations over the tropical Atlantic are enhanced throughout the year. During boreal summer (wet season), the O₃ maximum is generally located close to the West African coast around –10° S but O₃ enhancements can extend further north (up to 5° N) and south (–20° S). Layers with enhanced O₃ have been observed in ozone sonde data in the mid and upper troposphere over the Atlantic Ocean (Thompson et al., 1996a; Jenkins et al., 2008) and over West Africa (Thouret et al., 2009) during the summer monsoon period.

Two processes have been suggested to explain this O₃ maximum: 1) photochemical production of O₃ following NO_x (nitrogen oxide (NO) + dioxide (NO₂)) release by lightning (LiNO_x) associated with deep convection has been proposed to explain enhanced O₃ observed above 700 hPa (Jacob et al., 1996; Jenkins and Ryu, 2004b); 2) production of O₃ in BB plumes. The relative importance of these 2 processes is still not well quantified. Whereas some studies suggest a comparable importance, Sauvage et al. (2007a) suggested that annual O₃ production from BB sources only represents 1/4 of that from LiNO_x emissions.

As mentioned earlier, in Africa, BB regions are located south of the equator during boreal summer. Direct westward transport to the ocean of BB air masses could explain O₃ enhancements between –10 to –20° S but in order to contribute to enhanced O₃ at more northerly latitudes than –10° S, BB emissions must be transported to equatorial latitudes. This hypothesis is supported by several recent studies (Sauvage et al., 2005; Mari et al., 2008; Jenkins et al., 2008). Sauvage et al. (2005) first suggested that O₃ transport from central Africa to West Africa in the MT could explain 30% of enhancements observed in ozone sonde data. In a later analysis of ozonesonde data collected at Cotonou (Benin) on the southern coast of West Africa, Thouret et al. (2009) showed that these mid-troposphere enhancements are more frequent in August than in June or September and exhibit a strong inter-annual variability. During these years they estimated that during June–July–August (JJA), 41% of sampled layers exhibited mid-troposphere O₃ enhancements. They also showed that during JJA the vertical layer contributing the most to tropospheric O₃ columns is the 500–250 hPa layer. However, during August, layers below 500 hPa accounted for half the total column. Mari et al. (2008) also investigated the variability in the transport of BB emissions

from central Africa to the gulf of Guinea (West Africa) and the Atlantic Ocean in the mid-troposphere during July and August 2006 and suggested that it is driven by variations in the southern branch of the African Easterly Jet. During periods when this jet is less active, BB emissions can be trapped over the continent and injected into the upper troposphere by deep convection. However, the relative importance of mid-level versus upper level transport of BB emissions was not studied in detail.

Whilst, pathways for the transport of BB emissions out of central Africa have been identified and related to vertical ozone sonde data or to data collected by the MOZAIC programme in the upper troposphere (Mari et al., 2008; Thouret et al., 2009; Sauvage et al., 2007b), the relative importance of mid versus upper tropospheric transport are still not well quantified. The potential of these BB air masses to produce O₃ downwind of the emission region and their contribution to the O₃ maximum over the southern Atlantic Ocean are also still very uncertain.

In this paper, we examine, in detail, using tracer simulations from a mesoscale model, the origin of two pollution plumes observed in the Mid Troposphere (MT) and Upper Troposphere (UT) during August 2006 over the southern coast of West Africa during the AMMA (African Monsoon Multidisciplinary Analysis) project.

Thanks to a high altitude aircraft this was the first time that trace gas and aerosol measurements were performed in the upper troposphere over West Africa. The plume observations are discussed in Sect. 2). The high levels of trace gas emitted in fire (CO, CO₂, acetonitrile) and of aerosols suggest a BB origins. Confirmation of their origins and transport pathways to West Africa are then investigated using fire CO tracers run in a mesoscale model (Sect. 3). The results from these simulations are used to quantify the mechanisms responsible for transporting the plumes from the Southern to the Northern Hemisphere where they were observed in the MT and UT over West Africa. In particular, we use the results to diagnose the travel times between the source region and the region where the observations were collected as well as the fraction of tracer transported into the UT compared to the MT. We also estimate, based on photochemical trajectory model simulations initialised with plume concentrations, net photochemical O₃ production rates in the MT and UT central African BB plumes during transport downwind over the Atlantic (Sect. 4). The results are discussed in the context of the possible contribution of BB emissions to the Atlantic O₃ maximum and previous studies. Conclusions are presented in Sect. 5.

2 Observational evidence

During August 2006, five aircraft equipped with trace gas and aerosol instrumentation made flights over West Africa as part of an AMMA special observing period with the aim

to improve understanding about processes influencing atmospheric composition over this region. An overview of the main findings from this campaign is given in Reeves (2010) including details about instrument payloads and flights. Here, we focus on the analysis of plumes observed in the MT and also in the UT on 13 August 2006 when 4 aircraft flew to the Gulf of Guinea (UK BAe-146 (B-146), French Falcon-20 (FF20), DLR Falcon-20 (DF-20) and the M55-Geophysica (M55)).

First considering the MT plume(s), layers with high concentrations of CO, CO₂, peroxyacetyl nitrate (PAN), NO_x, O₃, acid nitric (HNO₃) Volatile Organic Carbons (VOCs) and aerosols were sampled between 2.5 and 4.5 km by the B-146, and 3 h later by the DF-20 below 5.5 km (500 hPa) over southern West Africa and the Gulf of Guinea (see Figs. 1, 2 and Table 1). For example, the DF-20 measured up to 450 ppbv CO, 130 ppbv O₃ and more than 8 ppbv NO_y (NO+NO₂+PAN+HNO₃ etc.) (see Fig. 2). The NO:NO_y was rather low (0.04) indicating that significant photochemical processing had taken place and therefore discounting local anthropogenic emissions as the origin. The FF-20, which flew to the same region, also sampled air masses with elevated CO and O₃ at around 8 km at 6° N on the same day with an origin over the Gulf of Guinea according to Ancellet et al. (2009). The B-146 observed rather similar CO and O₃ concentrations especially in the upper part of their plume sampling suggesting that both aircraft sampled the same polluted air mass. The B-146 also sampled high concentration of PAN (greater than 800 pptv) together with high acetonitrile concentration, a strong indicator of BB emissions (Reeves, 2010). The DF-20 plume also had high CO₂ concentrations up to 390 ppmv (mean value of 387 ppmv). These observations strongly suggest the presence of a large BB plume over the Gulf of Guinea extending between about 3 and 6 km: denoted the MT plume in the rest of the paper. Interestingly, data collected on the 4 August 2006, when a similar flight was made over this region, also showed evidence for BB plumes with elevated trace gas and aerosol concentrations, including CO₂ up to 379 ppmv Andres-Hernandez et al. (2009).

The high altitude M55-Geophysica (M55) aircraft also flew on this day (see Cairo et al., 2010 for a discussion about the aircraft campaign and payload). Interestingly, a plume was observed by the M55 during a dive over the Gulf of Guinea down to 200 hPa (12 km): denoted the UT plume in the rest of the paper. Observations showed elevated concentrations of trace gases (see Fig. 3) and aerosols. Measurements of CO₂ in the dive (around 380 ppmv) were higher than measured at similar altitudes during the rest of the campaign (see Fig. 3b). Higher CO₂ concentrations in the Tropical Tropopause transition Layer (TTL) are usually attributed to uplift of mid-latitude air masses several months earlier when surface concentrations are higher (e.g. Park et al., 2007). However, CO₂ concentrations are also elevated in BB air masses (as in the MT BB plume observed by the DF-20

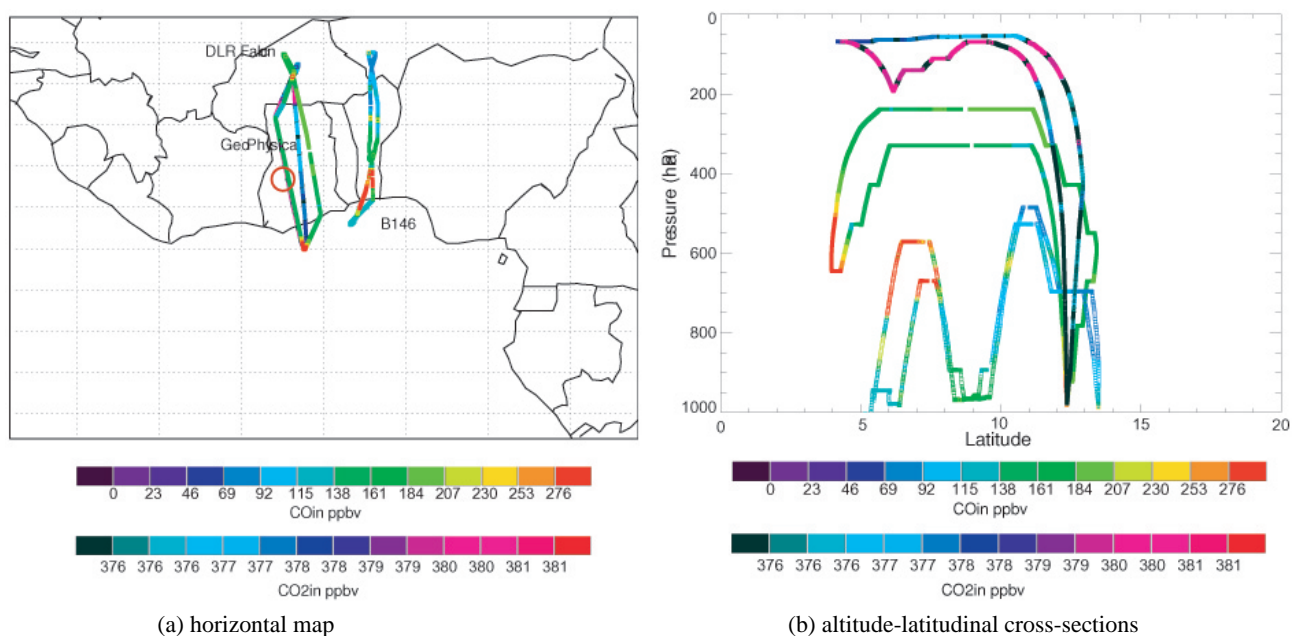

Fig. 1. Flight path for 13 August 2006 flight. Colour scales represent the CO concentrations from the DF-20 and the B-146 and CO₂ concentrations for the M55 aircraft. See text for details.

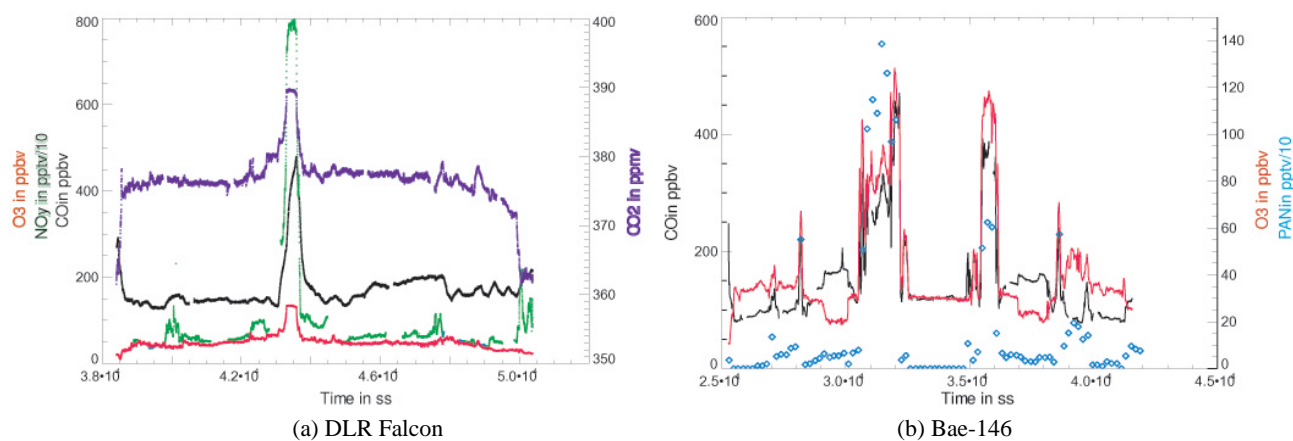

Fig. 2. Measurements taken on 13 August 2006 by the DLR Falcon aircraft (left hand) and the Bae-146 (right hand).

on the same day). O₃ concentrations were around 60 ppbv which is in the upper range of measurements collected at these altitudes during the rest of the M55 campaign (Law, 2010) and also compared to average tropical profiles reported in Fueglistaler et al. (2009) which show a minimum in the upper troposphere at these altitudes attributed to uplift of O₃-poor air. NO and NO_y were also higher during the plume sampling with up to 300 pptv NO and 1 ppbv NO_y. Whilst, these NO_y concentrations are not very elevated (Voigt et al., 2008) the fact that the NO:NO_y ratio is around 0.3 suggests that this air mass may also have been influenced by more recent LiNO_x emissions associated with deep convection. This point is discussed further in Sect. 4.2.

The M55 plume also showed slightly elevated concentrations (up to 10 000 molecules per milligram of air) of fine-mode aerosol. This is in the upper range of measurements collected at these altitudes during the rest of the campaign (Borrmann et al., 2009). The fact that particle concentrations for sizes less than 6 nm and less than 14 nm are very similar indicates that no new nucleation had recently taken place. Analysis of other flights (4 and 11 August 2006) when measurements of the non-volatile fraction are also available show that a significant fraction (up to 60%) of particles in the lower TTL were non-volatile and contained soot or non-volatile organic aerosols suggesting injection from a surface source such as BB emissions could be influencing upper

Table 1. Mean concentrations and standard deviations (in brackets) measured in the MT plume by the Bae-146 and the DLR Falcon aircrafts. No standard deviations are given for hydrocarbons as they result from one sampling measurement. Concentrations used to initialise the box model calculation are given in the third column. In case both aircrafts measured the same species, the average is calculated. HNO_3 is calculated as the sum: $(\text{NO}_y - \text{PAN} - \text{NO}_2 - \text{NO})$. Background concentrations are taken from Jacob et al. (1996) (4–8 km).

| | Bae-146 | DLR Falcon | Initialisation | background concentrations |
|---------------------------------------|------------|-------------|----------------|---------------------------|

Fig. 3. Right hand figure: Measurements of NO, NO_y and O₃ taken on 13 August 2006 by the GeoPhysica. Left hand figure: Measurements of CO₂ taken during the whole campaign, CO₂ measured during the dive on the 13 August is highlighted in red.

tropospheric aerosol composition over West Africa (Bormann et al., 2009). Finally, whilst CO was not measured on this day by the M55, the DF-20 and the FF-20 (Ancellet et al., 2009) also sampled plumes with elevated CO at around 11 km over the southern coast of West Africa (see Fig. 2). Analysis of MOZAIC data collected between 1 to 16 August 2006 in the upper troposphere also shows the existence

of several plumes between the Equator and 5° N with CO concentrations above 150 ppbv and, in one case as high as 230 ppbv in the upper troposphere (240 hPa) (J. P. Cammas, personal communication, 2009) Examination of air mass origins in the TTL (350–380 K, 250 to 50 hPa) for this campaign using ensembles of back trajectories from both the M55 flight paths and the TTL region over West Africa showed that 10

to 15% of the measured air masses up to 150 hPa probably originate from central Africa during the period 13 to 16 August.

In summary, it appears that the MT plume(s) has the characteristics of a BB origin with high concentrations of trace gases (including BB tracers) and aerosols. Considering the UT plume, high CO₂ concentrations indicate a BB origin but the air mass may also have been influenced by LiNO_x. In the next section we examine the transport mechanisms responsible for transporting BB plumes originating from central Africa to the MT and UT over West Africa. The possible LiNO_x influence is discussed further in Sect. 4.

3 Cross-hemispheric transport of BB plumes: mechanisms and travel times

3.1 Meteorological situation

The circulation over West Africa during the summer monsoon is dominated by the northward migration of the Inter-Tropical Front denoting the convergence between south-westerly monsoon winds and north-easterly dry Harmattan winds, and associated westward propagation of organised mesoscale convective systems linked to the position and strength of the African Easterly Jet (AEJ). The 2006 monsoon was characterised by slightly higher convective activity (stronger AEJ) than average and an intertropical convergence zone at 10° N in August. The upper level tropical easterly jet, positioned at around 5° N was also stronger in August 2006 with a slight north-east/south-west tilt compared to its mean position. For further discussion about the meteorological situation during the wet season in 2006 compared to other years see Janicot et al. (2008).

As discussed in the Introduction, Sauvage et al. (2006) attributed mid-tropospheric O₃ enhancements over the southern coast of West Africa to direct transport of BB plumes in the mid-troposphere during the summer monsoon. This transport pathway is associated with a convergence zone at 5S over central Africa followed by transport by south-easterly trade winds over the Gulf of Guinea. Mari et al. (2008) further investigated cross-hemispheric transport of BB pollution during July and August 2006 using of fire tracer simulations in the FLEXPART model. They examined the relationship between the intrusion of BB emissions into West Africa, and the strength of a mid-level jet over central Africa. This jet previously identified by Burpee (1972); Nicholson and Grist (2003), and denoted African Easterly Jet south (AEJ-S) in Mari et al. (2008) had a mean position around 5° S and 700 hPa in 2006. Mari et al. (2008) found that during so-called AEJ-S active phases (25 July to 2 August 2006; 10 to 31 August 2006), this jet extended westwards over the ocean thus driving lower tropospheric intrusions of BB plumes over the Gulf of Guinea. During break phases (3 to 9 August 2006) such transport is inhibited and BB pollutants

remain trapped over the central African continent. Whilst Mari et al. (2008) suggested that BB plumes can also be uplifted by deep convection into the upper troposphere followed by westward transport by the tropical easterly jet they did not examine this second transport pathway in detail. Here, we use a mesoscale model, BOLAM (Bologna Limited Area Model) Buzzi and Foschini (2000), to quantify the relative fractions of BB pollutants transported in the UT compared to the MT and to investigate how long it took the pollutants to arrive over southern West Africa where the measurements were taken. We also use the model results to estimate dilution rates for the UT plume in the chemical trajectory model calculations.

3.2 Model description and simulation set up

BOLAM is a limited-area, primitive equation, terrain-following coordinate, hydrostatic meteorological model. A detailed description of the dynamics and numerical schemes of the model can be found in Malguzzi et al. (2006). The main prognostic variables are the wind components (u and v), the potential temperature, the surface pressure, and the specific humidity. The water cycle for stratiform precipitation is described by means of five additional prognostic variables: cloud ice, cloud water, rain, snow, graupel. The horizontal discretization is based on a (staggered) Arakawa C grid, in geographical coordinates (latitude-longitude). Deep convection is parametrized using the Kain-Fritsch convection scheme, recently updated on the basis of the revision proposed by Kain (2004).

The model simulations discussed here were run over the domain shown in Fig. 4 with a horizontal resolution of 0.26°×0.26° and 38 hybrid sigma vertical levels from the ground to 10 hPa. The model was initialized using 0.5°×0.5° European Centre for Medium Range Weather Forecast (ECMWF) meteorological analyses at 00:00 UT on 15 July 2006 and run for 32 days until 00:00 UT on 16 August 2006. ECMWF analyses were also used to update the lateral boundary conditions every 6 h. Time-varying CO-like BB tracer emissions were introduced into the model for the duration of the run. Daily fire emissions were interpolated from 5-day running-mean averaged emissions taken from the AMMA African BB inventory compiled by Lioussé (2010), specifically for 2006. Separate tracers were injected daily for 24 h up to an altitude of 1 km and then transported for the rest of the simulation, in order to follow the fate of BB plumes emitted on each day of the run. Figure 5 shows the BB CO emissions averaged between 15 July and 15 August 2006 together with the ECMWF wind field at 750 hPa averaged over the same period. The two transport pathways for the BB plumes in lower troposphere to the north-east and north-west can be seen.

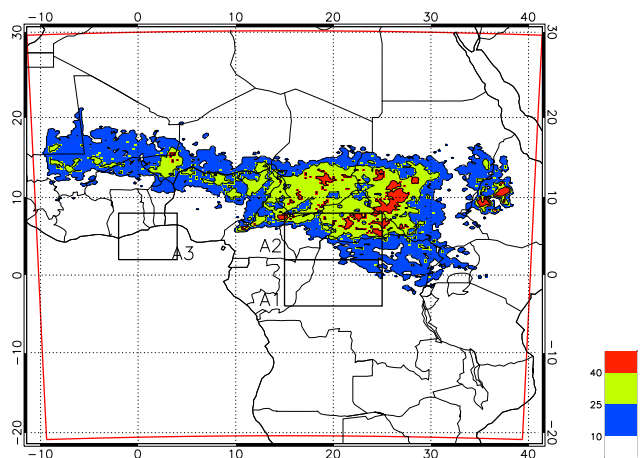

Fig. 4. Percentage of cloud cover for model-derived cloud top brightness temperature less than 230 K. Cloud Percentage is relative to the period 15 July–15 August. Black squares indicate the averaging area used in Fig. 7. Red box indicates the BOLAM model domain.

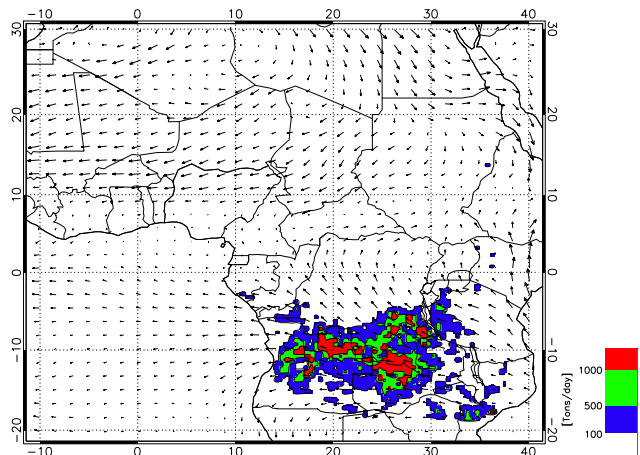

Fig. 5. CO flux averaged between 15 July and 15 August. Thin arrows are ECMWF wind field averaged between 15 July and 15 August at 750 hPa.

3.3 BB tracer results

In this section the model capacity to reproduce convective activity was first evaluated. Then the model time distribution of BB tracers was studied (from 15 July to 15 August), showing the episodic nature of transport in equatorial regions both in the UT and the MT. Different pathways for UT and MT plumes were simulated and the ratio of tracers transported in the UT to those transported in the MT was evaluated and compared with measurements. Finally the plumes age over West Africa were evaluated using modelled tracers.

The performance of the BOLAM model in reproducing convective activity was evaluated using cloud top brightness temperatures derived from the 10.8 micrometer channel of the SEVIRI radiometer, on-board of Meteosat Second

Fig. 6. Percentage of cloud cover for cloud top brightness temperature less than 230 K, evaluated from MSG-SEVIRI radiometer. Percentage is relative to the period 15 July–15 August. Thin arrows are ECMWF wind field at 250 hPa averaged over the same period.

Generation satellite. These values were compared with cloud top brightness temperatures calculated using the RTTOV-8 (Proceedings of the Fourteenth International TOVS Study Conference Conference; Beijing, 2005) radiative transfer model and BOLAM water vapour, temperature and hydrometeor profiles. The percentage cloud cover with cloud top temperatures less than 230 K together with ECMWF winds at 250 hPa are shown in Fig. 6. The figure shows the regions with greater convective activity and the tropical easterly jet that transports the air masses uplifted by deep convection toward West Africa. Figure 4 shows the percentage of cloud cover calculated from the BOLAM model for the same period. The model reproduces reasonably well the structure and intensity of convective activity. The meridional position of the intertropical convergence zone in West Africa is displaced northward in the model by about 5 degrees while its northern extent in Sudan and Chad is well simulated. However, BOLAM simulates less convective activity in Democratic Republic of Congo, Cameroon and Nigeria and overestimates convection in Central African Republic, Sudan and Chad.

Figure 7 shows the time evolution of tracer profiles averaged over three different areas highlighted in Fig. 4. In these and subsequent figures we only display CO tracers which are 20 days old or younger based on estimates of the chemical of CO lifetime in the lower tropical troposphere (Mauzerall et al., 1998). Area A1 is located just to the north of the emission region and area A2 is located further north. Note that results are not shown below 900 hPa over these regions due to the presence of mountains. Area A3 is located in the region where the aircraft observed the polluted plumes on 13 August. Significant tracer arrives in A1 and A2 in the mid-troposphere starting on 17 July in the region A1, and later from 22 July in A2. There is significant variability in the modelled tracer transport which depends on the

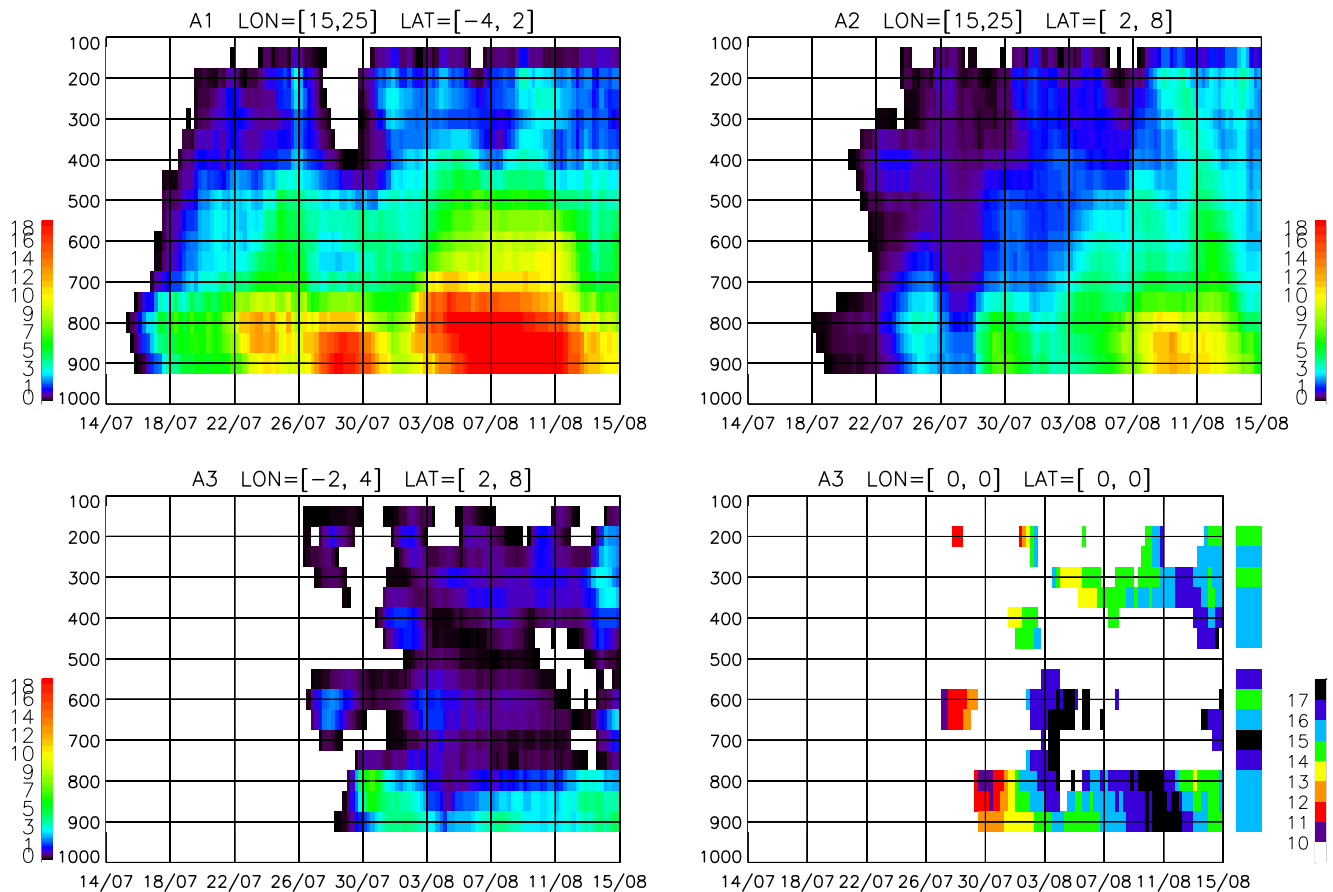

Fig. 7. Time-pressure plot of tracer concentration (in tracer units) averaged over areas A1, A2 and A3 (top left, top right and bottom left, respectively). Time-pressure plot of tracer travel time for area A3 (bottom right). Travel time is given in days.

daily position of fires and the intensity of the low level winds. Three episodes of high BB tracer concentrations are visible in A1 in the lower troposphere. The one between 3–11 August 2006 corresponds reasonably well with the break phase of the AEJ-S described by Mari et al. (2008) when pollutants build up over the continent, even if the model has higher concentrations and simulated tracers for longer over this region than simulated by Mari et al. (2008). Injection into the UT is also episodic and depends on the position of convective activity relative to the availability of pollutants (tracer) at lower altitudes. There is a clear increase in MT and UT tracer after the 5 August, especially in A2 where the convection is located (see Fig. 6). At mid-levels (around 650 hPa) over West Africa enhancements in A3 tracer concentration are seen between 27–29 July, 2–5 August and after 14 August. In the UT tracer arrives, albeit with low values, around 1 August with a more intense peak after the 14 August. This later enhancement corresponds well with the plume location measured by the M55 even but the modelled plume arrives 1 day later. The plume is quite dispersed in the vertical. This may be realistic since the DF-20 may have also sampled a BB plume in the UT around 11 km (see Sect. 2).

Examination of tracer concentrations at different altitudes shows that the MT and UT BB tracer follow different pathways. During the break phase (e.g. 3–11 August in the model) what becomes UT tracer is uplifted by wet convection in the area around the equator spanning longitudes between 15° and 25° E, and in the area around 5° N 22° E. The MT tracer is transported into the mid-troposphere south of the equator between 10° and 23° S, where wet convection is absent according to the model and less intense according to the satellite cloud measurements (see Figs. 6 and 4). Then, it is transported vertically by both dry convection and the baroclinic cell previously described by Sauvage et al. (2005).

The ratio of tracer in the UT versus MT ($\frac{\text{Tracer}_{\text{UT}}}{\text{Tracer}_{\text{MT}}}$) can be estimated using observed CO₂ enhancements above background in both plumes and compared with results from the BOLAM model. Enhancements of about 11 ppmv and 4 ppmv are measured for the MT and UT plumes, respectively (see Figs. 2 and 3) giving a measured ratio of around 0.36. Taking into account the 24 h delay in higher modelled concentrations reaching the measurement location, we use model results on 14 and 15 August to estimate the modelled ratio of UT (200 hPa) to MT (650 hPa) tracer. The area

selected to evaluate the ratio was chosen to contain almost all the plumes and spans from 10° S to 15° N and 10° W to 10° E. The UT:MT ratio varies between 0.3 and 0.6 between 14–15 August, with an average of 0.42 over this period which is similar to that derived from the CO₂ measurements. Values inferred from Mari et al. (2008) suggest a lower fraction transported into the upper troposphere (0.05–0.2) based on study using FLEXPART driven with ECMWF winds over the region encompassing 30W–10E. The UT:MT ratio was also calculated for a longer period from 1–15 August. To take into account the variability of the vertical position and thickness of the plumes, two pressure layers were used: 800 hPa–500 hPa and 500 hPa–150 hPa. 500 hPa was chosen since the model shows a discontinuity in tracer concentration at this altitude which can be interpreted as the transition between the UT and MT transport pathways. The ratio over this period varies between 0.25 and 1, giving 0.6 on average. Therefore, according to the model, a significant fraction (higher than previously reported) of BB emissions can be transported into the UT but this fraction remains lower than those transported in the MT. These differences in tracer concentrations are due to 1) the fact that wet convection is needed to inject tracer in the UT and 2) higher mixing of tracer when transported in the UT. This more intense mixing is due to both uplift by deep convection and dispersion by wind fields. In fact, entrainment and detrainment of ambient air within the vertical column is taken into account in the model convective parametrization leading to tracer mixing with cleaner air masses. Furthermore, dispersion occurs in the outflow region due to divergent winds that form at the top of the uplift column.

Since we emitted one tracer per day the results can also be used to estimate the time since emission as a function of altitude. This time since emission is obtained from a mean age of the tracers on each day, weighted by their concentrations. Results over A3 are shown in Fig. 7 averaged over the whole simulation period. The time for the tracers to arrive over West Africa with maximum modelled concentrations in the UT (14 August) at 200 hPa is 14 to 15 days whereas the MT plume takes between 16 to 17 days. An estimate of the time needed by pollutants to travel between areas A1/A2 and area A3 was also estimated by dividing the longitudinal distance between the centres of areas A1 and A2 (20° E) and the centre of area A3 (1° E) by the zonal wind speed averaged between 11–15 August and averaged over the region encompassing areas A1, A2 and A3 (4° S and 8° N; 2° W and 25° E). We derive a transit time of 4–5 days for the MT plume and 1–2 days for the UT plume. This is faster than the 8 days reported by Sauvage et al. (2005). However, that study was based on a climatological (1997–2003) analysis of MOZAIC profile data, and could be due to differences in wind speeds between different years. Our results suggest that this transport can be much faster in certain cases.

In summary, the modelled tracer results support the hypothesis of direct mid-troposphere transport of BB plumes

from central Africa to the southern coast of West Africa. These MT plumes contain high pollutants concentrations due to the time spent in the vicinity of the emission regions. We also show that BB pollutants transported further north can be uplifted into the UT by wet convection, and transported westward to the measurement region over West Africa. These plumes exhibit lower concentrations probably due to enhanced mixing. For the 1–15 August period a ratio between tracers concentration in the UT and the MT of 0.6 was evaluated over a region encompassing West Africa and the eastern part of equatorial south Atlantic.

4 Ozone production in plumes transported downwind of West Africa

In this section, we address the question about whether these BB plumes continue to produce O₃ downwind from where the measurements were taken, i.e. over the equatorial South Atlantic. A photochemical model, CiTTyCAT (including 90 chemical species, see Evans et al., 2000; Real et al., 2007 for details) was initialized with mean concentrations taken from available measurements and run forwards for 10 days along selected air masses trajectories. The trajectories were calculated from the location of the BB measurements (MT and UT) using the FLEXTRA model (Stohl et al., 1995) run with ECMWF wind fields (see Fig. 8). The MT plume was transported over the southern Atlantic Ocean before reaching the south American east coast. The UT plume was also transported over ocean but it recirculated back to the central African coast. Simulations of the chemical fate of both plumes were carried out including diagnosis of photochemistry versus mixing/dilution of the plume with background air, and the impact of aerosols on photolysis rates for the MT plume.

4.1 Chemical fate of the MT plume

4.1.1 Model set-up

On 13 August 2006, the B-146 sampled the lower part of the plume, followed 3 h later by the DF-20 sampled its upper part. Since these plumes have very similar origin measurements can be combined to provide mean values to initialize the model MT plume simulations (see Table 1). Forward trajectories initialized in the plume show similar directions but different altitudes at the end between 1.5 and 6.5 km. One trajectory was chosen to conduct the main simulations (black one in Fig. 8) and a sensitivity test regarding the choice of trajectory is presented in Sect. 4.1.3.

For the main simulations, three runs were conducted: chemistry-only (Run-CHEM), chemistry plus impact of aerosols on photolysis rates (Run-AER) and chemistry plus aerosols plus mixing/dilution of the plume (Run-MIX). To simulate aerosol impacts on photolysis rates, the FAST-J scheme (Wild et al., 2000) was used (see Real et al., 2007 for

Fig. 8. 10 days simulated forward trajectories initialised from the MT plume and the UT plume. 3 MT trajectories were chosen to perform MT run (green, black and orange bold lines) and one trajectory for the UT run (pink bold line). Flight tracks of the DLR Falcon, the BAe-146 and the GeoPhysica aircrafts are represented as red dashed lines.

Fig. 9. CALIPSO images during the paths of 13 August over the Gulf of Guinea (right hand) and over the SAO on 20 August (left hand). Plumes with high concentrations of aerosols are visible between 2 and 5 km.

details). This scheme requires information about the aerosol optical depth (AOD) of the aerosol layer and aerosol optical properties. Refractive indices ($R_i=1.54-0.078$) and aerosol size distributions were taken from measurements made in aged BB plumes from a South African fire (Haywood et al., 2003), and used to calculate optical properties using a Mie code (Mishchenko et al., 1999). The 550 nm AOD was retrieved from MODIS satellite measurements (Tanre et al., 1997; Remer et al., 2005) which passed over the Gulf of Guinea on 13 August, and over south Atlantic 7 days later. The collocated CALIPSO lidar data (Winker et al., 2003) clearly show that the main AOD contribution is due to the presence of an aerosol layer between 4 and 6 km on 13 August, and also on 20 August albeit less intense (see Fig. 9).

MODIS Aqua aerosol level 2 products version 5 (MYD04) and CALIPSO level 1 version 2 data (532 nm total attenuated backscatter) were used in this analysis. An AOD of 0.9 on 13 August and 0.3 on 20 August were estimated for the aerosol layer. Therefore, in Run-AER the AOD was allowed to decrease linearly from 0.9 during the first 7 days and then held constant at 0.3.

The dilution of trace gas concentrations in the MT plume were simulated as an exponential decay toward background concentrations with prescribed mixing rates based on measurements as far as possible. This treatment of mixing of a plume has been used previously, and is detailed in Evans et al. (2000); Real et al. (2007). Assuming no physical changes in aerosols during transport (ECMWF analyses do

Fig. 10. Simulated concentrations in the MT plume for case RUN-CHEM (black lines), RUN-AEROSOL (red lines) and RUN-MIXING (blue lines).

not show any precipitation along the trajectory) and a zero aerosol background, observed decreases in AOD were used to estimate a mixing rate of 6.4 days. This mixing rate compares well with values estimated by Real et al. (2007) at mid-latitudes in the free troposphere under meteorological conditions dominated by large-scale advection, which is also the case for the MT plume studies here. For background concentrations, mean measurements taken between 4–8 km during the TRACE-A campaign over the southern Atlantic, and reported in Jacob et al. (1996) were used (see Table 1).

4.1.2 Results

Changes in simulated MT plume concentrations during 10 days are shown in Fig. 10 for Run-CHEM (black continuous line), Run-AER (red dashed line) and Run-MIX (blue dotted line). Run-AER simulates slightly lower O_3 and higher CO than Run-CHEM although changes are small. Run-MIX, which represents the more realistic run, generally produces lower concentrations of all species compared to Run-AER due to mixing with cleaner air masses. Mixing has less impact on more reactive species such as NO_x and also, PAN which is mainly influenced by temperature-driven decomposition.

Before describing chemistry going on in the plume, we sum-up the main processes influencing O_3 concentrations in the troposphere. O_3 is produced by the photolysis of NO_2 and destroyed by reaction with NO. In the presence of carbonaceous species (VOC, CO or CH_4) additional O_3 can be formed due to the additional formation of HO_2 and higher peroxy radicals. O_3 can also be destroyed by photolysis in presence of water vapour or reaction with OH or HO_2 . NO_2 mainly recycles with NO but can be stored in reservoir species such as PAN or HNO_3 . Thermal decomposition of PAN (under high temperatures) or photolysis of HNO_3 can release NO_2 back into the atmosphere leading to additional photochemical O_3 production.

Net photochemical O_3 production (NPO_3), given by the difference between photochemical O_3 production and loss, simulated along the trajectory is shown in Fig. 11 together with O_3 production and loss terms. In Run-CHEM, the plume exhibits a mean NPO_3 of about 4.7 ppbv/day during the first 4 days and slow net loss (−0.7 ppbv/day) during the last 6 days. This translates into a mean NPO_3 rate of 1.7 ppbv/day over 10 days. Photochemical O_3 production only decreases slightly over the 10 days due to a decrease in NO_x that is transformed into HNO_3 . Concerning O_3 destruction, it mainly follows water vapor content with decrease

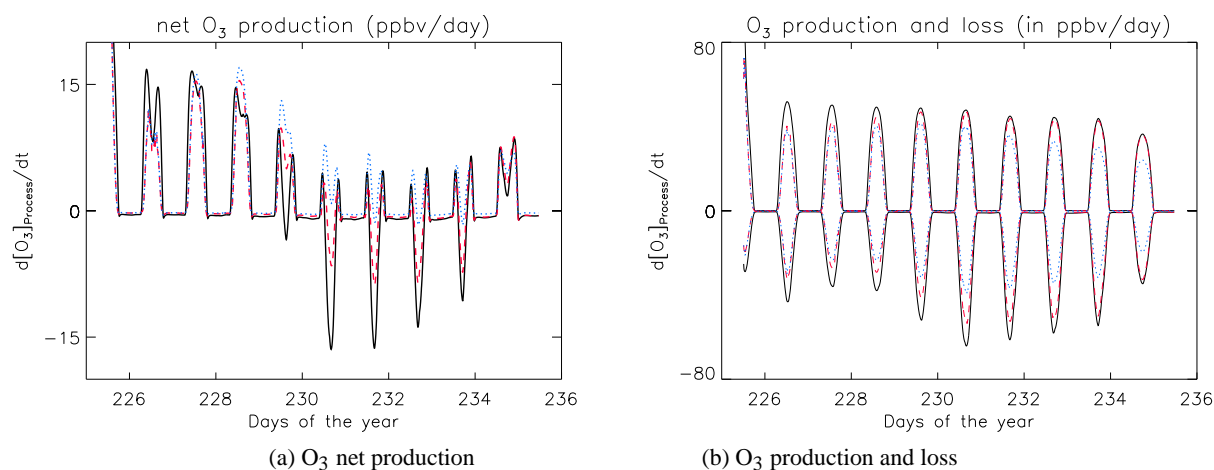

Fig. 11. 10 days simulated net O₃ production (left hand) and simulated production and destruction terms (right hand) in the MT plume.

during half of the simulation followed by increase. The production dominates until the 4th day of the simulation when increases in water vapour lead to additional O₃ destruction. Also, due to increasing O₃ concentrations, O₃ loss also increases via photolysis and reaction with HO₂.

Daily NPO₃s in Run-AER compared to Run-CHEM show strong differences: a –25% reduction during the first few days when there is net O₃ production, and a net increase in NPO₃ in Run-AER during the last 6 days when there is net O₃ loss. When averaged over 10 days, this leads to a mean NPO₃ in Run-AER which is only slightly lower compared to Run-CHEM (1.6 ppbv/day or 6% reduction). Indeed, because they absorb and scatter light, aerosols have the effect of reducing the photolysis rates of both NO₂ and O₃, and therefore O₃ production and O₃ destruction respectively. As already discussed in Real et al. (2007), when an air mass is in an O₃ destruction regime (O₃ loss higher than production), a similar proportional reduction of both O₃ production and destruction quantitatively reduce the destruction more than the production leading to less net O₃ destruction overall (see also Fig. 11). Inversely, in an O₃ production regime, O₃ production is reduced more than O₃ loss, leading to lower O₃ concentrations. One important difference between the 2 runs is that the O₃ maximum appears later in the Run-AER case.

In Run-MIX the mean NPO₃ is larger (2.6 ppbv/day) than without mixing. In this run, mean concentrations of O₃ precursors, like NO_x, are lower leading to a decrease in O₃ production. However, O₃ itself also strongly decreases due to mixing with clean air masses leading to a larger reduction in O₃ destruction compared to O₃ production, and therefore larger NPO₃. However O₃ concentration at the end of the simulation is lower than in Run-CHEM because of mixing with O₃ poor air masses.

In the 3 simulations O₃ production is maintained by two processes: PAN thermal decomposition during the subsidence of the plume due to increases in temperature,

and HNO₃ photolysis. Sensitivity runs without a) PAN decomposition and b) HNO₃ photolysis show that these processes contribute almost equally to NPO₃ in the plume. When both processes are removed, NPO₃ is negative. This shows that in this aged plume, O₃ production is not directly maintained by NO_x concentrations but by NO₂ from reservoir species: PAN and HNO₃. PAN has already been shown to play an important role in tropospheric O₃ production downwind from source regions (Heald et al., 2004). In particular, in BB plumes transported over the North Atlantic it was shown that PAN decomposition explain 80% of O₃ production (Real et al., 2007). The role of HNO₃ as a source of available NO_x for O₃ production is less well quantified with HNO₃ being mainly seen as a loss for NO₂. It has been shown that when HNO₃ concentrations are very high (>15 000 pptv), HNO₃ photolysis can maintain O₃ production in anthropogenic plumes transported over oceans at mid-latitudes (Neuman et al., 2006; Real et al., 2008). Here, HNO₃ concentration are not as high, but since the MT plume is transported at equatorial latitudes, photolysis rates are higher, and the role of HNO₃ as a source of O₃ is more important.

4.1.3 Sensitivity study on the trajectory used

Trajectories simulated with FLEXTRA initialized in the plume show that during transport over the Atlantic the plume is spread over different altitudes. Main simulations were conducted over a trajectory that stayed above 4 km. According to CALIPSO data on 20 August above the Atlantic, the plume spread between 1.5 and 5.5 km (also depending on the latitude). Therefore, we examine the sensitivity of the results to the choice of trajectory. The model was run along 2 additional trajectories, with same chemical initialization. The first was subject to a slow ascent up to 6 km (green trajectory on Fig. 8, R-HighLevel) and the second descended

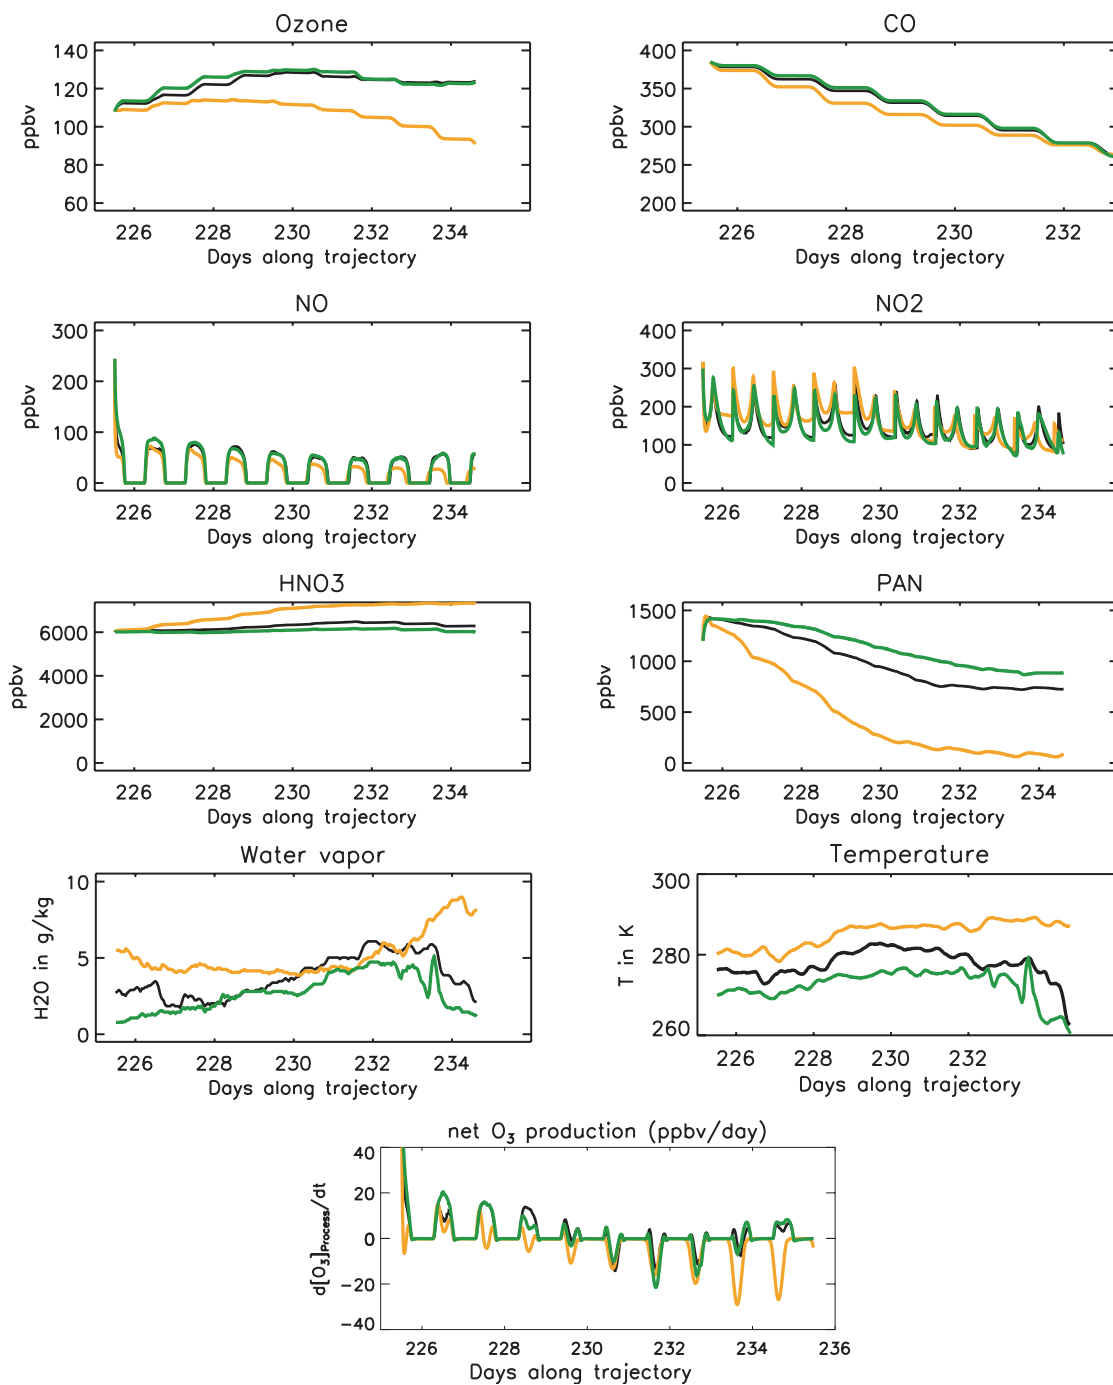

Fig. 12. Simulated concentration in the MT plume for case RUN-CHEM but for 3 different trajectories. Colours correspond to colours of the trajectories in Fig. 8: black for the reference trajectory, green for R-HighLevel and orange for R-Lowlevel. Simulated NPO_3 is also shown.

below 2 km (orange trajectory on Fig. 8, R-LowLevel). Results are shown Fig. 12 with no dilution and no aerosol impact. Temperature and water vapour simulated over the trajectories are also shown together with the net O_3 production. R-HighLevel and the reference run show similar O_3 concentrations. Temperature and water vapour are lower in the R-HighLevel trajectory that was transported at higher altitudes.

Lower temperatures lead to less PAN decomposition and less O_3 production but at the same time O_3 destruction is lower due to less water vapour. In the case shown here, these processes compensate each other resulting in little O_3 change overall. On the other hand, O_3 concentrations are very different between R-LowLevel and the 2 other simulations (around 25 ppbv after 10 days). R-LowLevel experiences

higher temperatures and water vapour concentrations. O_3 production following PAN decomposition is maintained during the first 4 days but when PAN concentrations are too low, strong O_3 destruction induced by the high water vapour dominates leading to negative NPO_3 overall. Mean NPO_3 simulated (with no dilution or aerosol impact) is 1.7 ppbv/day for the reference case against 1.6 ppbv/day for R-HighLevel and -2 ppbv/day for R-LowLevel. When including aerosol and mixing effects (not shown), NPO_3 is 2.5 ppbv/day for R-HighLevel and -0.5 ppbv/day for R-LowLevel (against 2.6 ppbv/day for the reference run). Final O_3 concentrations after 10 days are 80 ppbv (R-HighLevel) and 71 ppbv (R-LowLevel) when aerosol and mixing are included. Above the mid Atlantic (-20° W and -40° W), simulated O_3 concentrations are between 80 and 100 ppbv for trajectories above 4 km and 71–80 ppbv for the lowest trajectory (not shown). This study shows that NPO_3 in a plume transported over the Atlantic is very sensitive to the altitude of the transport with more O_3 production in the mid-troposphere compared to the lower troposphere where NPO_3 is negative.

4.1.4 Comparison with previous studies

The O_3 concentrations and NPO_3 rates presented in the previous section can be compared with O_3 measurements collected over the equatorial Atlantic and previous estimates of photochemical O_3 production rates in BB plumes transported over the southern Atlantic Ocean. Enhanced O_3 layers were observed over the Atlantic Ocean at equatorial latitudes by Jenkins et al. (2008). O_3 concentrations between 70 to 100 ppbv were measured in June 2006 mainly between 4 and 10 km. Below 4 km, plumes were not very pronounced with O_3 concentrations generally lower than 60 ppbv. O_3 concentrations between 80 and 90 ppbv between 3 and 12 km have also been observed at Ascension island (7.9° S, 14.40° W) which is at lower latitudes than the case studied here (Thompson et al., 1996a). Our estimated O_3 concentrations in the model runs including mixing over the Atlantic are in the same range of concentrations (80–100 ppbv), and also predict lower concentrations at lower altitude (71–80 ppbv). Jenkins et al. (2008) mainly observed layers with enhanced O_3 at higher altitudes in June 2006 than suggested by our results for August 2006. Thouret et al. (2009) also showed that enhanced layers were observed over West Africa at higher altitude in June than in August during 2005 and 2006.

As highlighted in Sect. 1, previous studies estimating photochemical O_3 production in BB plumes during transport downwind from South African BB regions showed O_3 net production close to the emissions and weak net O_3 destruction over the Atlantic (Mauzerall et al., 1998; Chatfield et al., 1996). In Mauzerall et al. (1998) the plume stayed above 4 km and in Chatfield et al. (1996) plumes were simulated between 3–6 km. Other studies based on measurements made over the Atlantic (and not over the continent as

in Mauzerall et al., 1998) estimates net O_3 production rates between 1–4 ppbv/day in the mid-troposphere (Jacob et al., 1996; Thompson et al., 1996a). This production was attributed to BB by Thompson et al. (1996a) and to both BB and lightning by Jacob et al. (1996). This latter also calculated net O_3 destruction (-0.7 ppbv/day) below 4 km.

When mixing is taken into account, we calculate a 10 day average NPO_3 around 2.8 ppbv/day above 4 km over the Atlantic and as high as 5 ppbv/day during the first 4 days of transport downwind from West Africa. These results suggest that this aged plume, which is already 16 days old at the beginning of the simulation, is still very photochemically active. Previous studies focused on younger plumes and did not take into account the impact of aerosols, which as we have shown may lead to a delay in the peak O_3 production. This effect could be particularly strong close to the fire emissions where aerosol optical depths are high and may partly explain the differences between our estimate and those from Mauzerall et al. (1998); Chatfield et al. (1996).

Following Thouret et al. (2009), O_3 enhancements in the free troposphere over West Africa are observed during 40% of the time in JJA 2005 and 2006 with an even higher occurrence in August 2006 (6 soundings over 7 show an O_3 enhancement). They suggested that these layers have BB origins. The BOLAM model results discussed earlier confirmed that MT plumes over West Africa are transported over the south Atlantic. Therefore, it can be estimated that the mid-troposphere over the equatorial South Atlantic is often impacted by BB air masses in JJA. With a mean O_3 production rate of 2.6 ppbv/day at 4 km over the ocean, pollutant plumes from BB regions are likely to have a significant impact on O_3 concentrations in the South Atlantic mid-troposphere. Simulated Atlantic O_3 concentrations are on the same level than measured in O_3 plumes suggesting that O_3 enhancements in the South Atlantic mid-troposphere may be mainly explained by BB sources. However a more thorough study with a chemistry-transport model that can correctly simulate BB transport and take into account aerosol impacts on photolysis rates as well as lightning NO_x is needed to better evaluate the contribution of BB emissions to the O_3 budget in this region.

4.2 Chemical fate of the UT plume

4.2.1 Model set-up

For the UT plume, two runs were performed with chemistry-only (Run-CHEM) and chemistry plus mixing (Run-MIX) along the trajectory highlighted in bold in Fig. 8. No simulation including aerosol impact on photolysis rates were performed because a) the aircraft only measured part of the plume during the dive making it difficult to estimate the real vertical dimension of the plume and its AOD, and b) aerosol concentrations were lower than for the MT plume possibly due to a less polluted UT plume or washout so any aerosol impacts are likely to have been smaller. Fewer trace gases

measurements were made by the M55 on 13 August which can be used to initialize the plume, namely O₃, NO_y, NO, and CO₂ (see Fig. 3) making it necessary to estimate other species (VOCs, CO, missing NO_y components). This means that the results presented here are not as well constrained as the MT case. Nevertheless, the model results can be used to provide an initial estimate of NPO₃ in the UT from a BB plume.

In order to estimate the missing values, measurements from the MT plumes sampled by the DF-20 and B-146 were used. Assuming plumes underwent the same chemical and physical transformations during transport from BB emission region, the fraction $\frac{\Delta\text{Species}}{\Delta\text{CO}_2}$ (where Δ is the difference between concentration in the plume and the background) should be approximately conserved between MT and UT $\left(\left(\frac{\Delta\text{Species}}{\Delta\text{CO}_2}\right)_{\text{UT}} = \left(\frac{\Delta\text{Species}}{\Delta\text{CO}_2}\right)_{\text{MT}}\right)$. This ratio is not modified by dilution or mixing since both species are affected to the same degree. According to Sect. 3, the plumes have approximately the same age so the level of oxidation in both plumes may not have been very different leading to small differences in CO and VOC lifetimes. By using measured $\left(\frac{\Delta\text{CO}}{\Delta\text{CO}_2}\right)_{\text{MT}}$ and $\left(\frac{\Delta\text{VOC}}{\Delta\text{CO}_2}\right)_{\text{MT}}$ combined with ΔCO_2 measured in the UT to obtain a UT ΔCO and ΔVOC , CO and VOC concentrations in the UT plume were derived. Background concentrations were estimated from background concentrations measured during the campaign by the M55 for CO, CO₂, NO, NO_y, O₃ and taken from Jacob et al. (1996) for VOCs and NO_y partitioning. The latter concentrations are typical values of tropical UT air masses (TRACE-A measurements over the south Atlantic)

On the other hand, $\frac{\Delta\text{NO}_y}{\Delta\text{CO}_2}$ (measured both in the UT and the MT) is not conserved between plumes and this ratio in the MT plume is much higher than the UT plume (500 pptv/ppmv versus 25 pptv/ppmv). This is most probably due to the fact that the UT air mass passed through a convective system with likely loss of HNO₃ (and other soluble gases and aerosols) by washout. Removal of HNO₃ by precipitation would also explain the high $\frac{\Delta\text{NO}}{\Delta\text{NO}_2}$ measured in the UT plume compared to the MT plume (due to loss of NO_y). Another phenomenon which could explain the high $\frac{\Delta\text{NO}}{\Delta\text{NO}_2}$ is lightning emissions of NO, but it does not explain the low UT $\frac{\Delta\text{NO}_y}{\Delta\text{CO}_2}$. Moreover NO in the UT plume is only slightly above mean NO measured by the M55 at that altitude during the campaign and a stronger NO signal would be expected if there had been recent lightning emissions. Therefore LiNO_x influence on the UT plume studied here cannot be completely excluded but it is unlikely. Finally, in order to estimate NO_y partitioning in the UT plume, $\frac{\Delta\text{PAN}}{\Delta\text{CO}_2}$ in the MT plume was used to derive UT PAN concentrations, NO₂ concentrations were estimated using modelled NO₂:NO ratios at steady state, and the rest of measured NO_y (NO_y – PAN – NO – NO₂) was attributed to HNO₃. All measured

Table 2. Mean concentrations and standard deviations (in brackets) measured in the UT plume by the M55 aircraft. Concentrations used to initialise the box model calculation are given in the second column (see text for details). Background concentrations are taken from Jacob et al. (1996) (8–12 km).

| | M55 | Initialisation | background concentrations |
|---------------------------------------|----------|----------------|---------------------------|
| CO (ppbv) | | 175 | 75 |
| O ₃ (ppbv) | 60 (7) | 60 | 50 |
| NO (pptv) | 220 (53) | 220 | 150 |
| NO ₂ (pptv) | | 200 | 10 |
| PAN (pptv) | | 330 | 223 |
| HNO ₃ (pptv) | | 70 | 59 |
| NO _y | 820 | | |
| C ₂ H ₄ (pptv) | | 6 | 9 |
| C ₂ H ₆ (pptv) | | 1000 | 670 |
| C ₂ H ₂ (pptv) | | 490 | 110 |
| C ₃ H ₆ (pptv) | | 1 | 4 |
| C ₄ H ₁₀ (pptv) | | 10 | |
| C ₅ H ₁₂ (pptv) | | 1 | |
| C ₆ H ₆ (pptv) | | 100 | 15 |
| C ₇ H ₈ (pptv) | | 3 | 2 |
| Formaldehyde (pptv) | | 400 | 40 |
| Acetone (pptv) | | 1070 | 650 |
| CO ₂ (ppmv) | 380 | | 376 |

and estimated values used to initialise the runs are reported Table 2.

In order to evaluate the mixing time to background for the UT plume, we used the BOLAM tracer results at 200 hPa where, as mentioned previously, 32 daily tracers were used to represent the day to day transport of CO BB emissions. Three days were selected when there was injection of tracer at 200 hPa over eastern/central Africa followed by decay and no new injection for several days afterwards. Using the hypothesis of an exponential decrease in the concentration toward a background value, a mixing time of 6 to 9 days was calculated using the linear regression of the logarithm of the maximum tracer concentration in the centre of the uplifted (model) plume as a function of time. Therefore, in Run-MIX we estimated a mixing timescale of 7 days.

4.2.2 Results

Results for RUN-CHEM are shown Fig. 13. As shown in Sect. 3, the UT plume is more diluted than the MT plume, and therefore O₃ precursor concentrations are lower. However, NPO₃ is only slightly smaller with a mean value over 10 days of 1.4 ppbv/day compared to 1.6 ppbv/day for the MT plume (chemistry only). In fact both photochemical production and destruction of O₃ are smaller than in the MT plume (about only 10% of the MT values). Simulated O₃ concentrations after 10 days are about 72 ppbv in this chemistry only run. Since there are uncertainties in the initial concentrations used, especially for the VOCs, we performed a

Fig. 13. 10 days simulated concentrations in the UT plume in the case RUN-CHEM (black line) and RUN-MIXING (blue lines).

sensitivity test where the initial VOC concentrations were doubled. NPO_3 changes by only 10% whereas doubling NO_x concentrations induces a NPO_3 increase of 40%. These results show that the UT plume is NO_x limited, and therefore NPO_3 not very sensitive to initial VOC concentrations. The NO_x are better constrained by the measurements.

Inclusion of mixing leads to decreases in O_3 concentrations to around 60 ppbv whereas CO concentrations decrease by about 35 ppbv. Mean NPO_3 only slightly decreases to 1.3 ppbv/day resulting in the maintenance of O_3 concentrations despite mixing with lower background concentrations. The mean NPO_3 for the UT plume with mixing is about half that for the MT plume.

Sensitivity runs using different trajectories only showed small differences (not shown).

4.2.3 Comparison with previous studies

Our results present, as far as we know, some of the first estimates of in-situ NPO_3 in UT BB plumes based on analysis of data. Other studies estimated O_3 budget (without sources differentiation) over the South Atlantic using global models (Moxim and Levy, 2000) or measurements (Jacob et al., 1996). They estimated net O_3 production rates of 1.5–2.1 ppbv/day in the UT over the south Atlantic. This number

is higher than our estimates of NPO_3 . Also, O_3 plumes observed in the South Atlantic UT generally exhibit O_3 concentrations between 80–100 ppbv when our simulation suggest 60 ppbv. However, the M55 may only have sampled the upper part of the plume during the dive over the Gulf of Guinea (see Fig. 1), and, as such, may not have sampled the highest concentrations. A less diluted plume would exhibit stronger O_3 production. MOZAIC data collected at 11 km during this period shows CO concentrations up to 240 ppbv which is higher than CO simulated in the UT plume (170 ppbv) in the case studied here. Therefore it is difficult to conclude on BB contribution to O_3 maximum on the UT. As our dynamic model BOLAM suggest sporadic transport in the UT and given the calculated NPO_3 in the UT plume it is unlikely that BB sources dominate this UT maximum but they can be an important contribution in some cases and need to be taken into account in global model simulations together with the important and more continuous source of enhanced O_3 from lightning NO_x emissions.

5 Conclusions

In this study we examined the origin and downwind O₃ production potential of pollutant plumes observed in the mid and upper troposphere over the southern coast of West Africa during August 2006 summer monsoon. Analysis of results from the BOLAM mesoscale model, including biomass burning CO tracers confirmed that the likely origin of the plumes was from biomass burning emission regions over central Africa. Model results showed BB pollutants confined over central Africa for between 12 days before being transported to the measurement region 4 days (MT plume) and 2 days (UT plume) later. According to the model both plumes are about 14 days old when measured over West Africa. The plumes observed in the mid troposphere had significantly higher pollutant concentrations than the plume observed in the upper troposphere. The mesoscale model reproduces these differences and shows two different pathways for the plumes at the different altitudes: transport to the north-east of the fire region, moist convective uplift and transport to West Africa driven by the tropical easterly jet for the upper tropospheric plume; north-west transport from the emission region to the Gulf of Guinea for the middle tropospheric plume. The UT:MT ratio of tracer concentrations at 600 hPa and 250 hPa was estimated to around 0.42 for the period 14–15 August in the region of the measurements which agrees well with the ratio derived from observed CO₂ enhancements in the plumes. Lower pollutant concentrations in the UT are mainly due to more dilution with cleaner air masses during upward transport. The same UT:MT fraction was evaluated over a larger period: 1–15 August and a mean value of 0.6 was simulated showing that even if injection of pollutants into the UT over West Africa is less frequent and plumes more diluted, it is significant, at least in the studied period (August 2006). This fraction is higher than previously suggested (Mari et al., 2008).

Net O₃ production downwind from West Africa was evaluated using a photochemical trajectory model initialized with the measurements. The mid-tropospheric plume was transported over the equatorial south Atlantic between 1.5 and 6 km. Simulations show that transport altitude strongly influences the resulting net O₃ production in the plume. Whereas below 2 km a net O₃ destruction was simulated, above 3 km, the plume produced O₃ with a mean rate of 2.6 ppbv/day over 10 days. During the first few days, this production even reached 7 ppbv/day. Our estimates of net O₃ production rates are higher than previously reported for aged BB plumes (16–26 days old here). We show that this net production is not directly due to transport of NO₂ but to NO₂ recycling by NO₂ reservoir species: PAN and HNO₃, which contribute equally. Model runs including the impact of aerosols on photolysis rates show that their main effect is to delay the maximum in O₃ downwind. This process may explain why previous studies estimated lower NPO₃ compared to this study. Given the possibility that aged BB plumes transported over the Atlantic

could be still very photochemically active, it is likely that this source is making a significant contribution (more than previously estimated) to O₃ levels in the MT. According to simulated occurrence of such transport, BB may even be the main source for O₃ enhancement in the equatorial south Atlantic MT, at least in August 2006. Slower net O₃ production rates and lower O₃ concentrations were simulated in the UT plume together with lower occurrence of transport.

In this study, we have focused on estimating in-situ O₃ production rates in a plume of BB origin. In order to understand the contribution from different O₃ sources to the O₃ maximum observed over the southern Atlantic it will be necessary to perform similar calculations for other important sources, and especially plumes influenced by LiNO_x. Indeed, even if simulated plume may not be representative of the more polluted BB plume in the UT, it seems that BB plumes are not the dominant source of O₃ production in the UT. As suggested in previous studies LiNO_x is probably more important to explain the UT maximum but this study show that BB may dominate the MT maximum. It would be interesting to estimate the importance of the MT maximum versus the UT maximum over the equatorial south Atlantic. According to Thouret et al. (2009) it may depend on the month of the year (with a maximum MT signal in August, equivalent to the UT signal). Simulations with a global chemistry model including aerosol impacts would be necessary to precisely and quantitatively estimate BB contribution to the O₃ maximum.

Acknowledgements. Based on a French initiative, AMMA was built by an international scientific group and is currently funded by a large number of agencies, especially from France, the United Kingdom, the United States, and Africa. It has been a beneficiary of a major financial contribution from the European Community Sixth Framework Programme (AMMA-EU). Detailed information on scientific coordination and funding is available on the AMMA International website at http://www.amma-international.org/rubrique.php?id_rubrique=1.

The DF-20 campaign was funded partly through AMMA-EU. The M55-Geophysica campaign was funded by AMMA-EU, EC Integrated Project SCOUT-O₃ (505390-GOCE-CT-2004), CNRS-INSU, CNES, EUFAR and the M55 aircraft consortium. We would like to thank all the scientists aircraft operators as well as local scientists and representatives in Burkina Faso for their help and support during the planning and execution of the Ouagadougou campaign. We also acknowledge support from the AMMA Operations Centre in Niamey, Niger.

The B-146 campaign was funded in part by AMMA-EU and also through a NERC AMMA-UK consortium grant. We also acknowledge B-146 data provided by the Facility for Airborne Atmospheric Measurements (FAAM) and the British Atmospheric Data Centre (BADC). E. Real acknowledges funding from the AMMA-EU.
