ABSTRACT

Voltage gated Kv7.4 channels have been implicated in vascular smooth muscle cells (VSMCs) activity as they modulate basal arterial contractility, mediate responses to endogenous vasorelaxants, and are down-regulated in several arterial beds in different models of hypertension. Angiotensin II (Ang II) is a key player in hypertension that affects the expression of several classes of ion channels. In this study we evaluated the effects of Ang II on the expression and function of vascular Kv7.4. Western blot and quantitative PCR revealed that in whole rat mesenteric artery Ang II incubation for 1-7h decreased Kv7.4 protein expression without reducing transcript levels. Moreover, Ang II decreased XE991 (Kv7) –sensitive currents, and attenuated membrane potential hyperpolarization and relaxation induced by the Kv7 activator ML213. Ang II also reduced Kv7.4 staining at the plasma membrane of VSMCs. Proteasome inhibition with MG132 prevented Ang II-induced decrease of Kv7.4 levels, and counteracted the functional impairment of ML213-induced relaxation in myography experiments. Proximity Ligation Assays showed that Ang II impaired the interaction of Kv7.4 with the molecular chaperone HSP90, enhanced the interaction of Kv7.4 with the E3 ubiquitin ligase CHIP, and increased Kv7.4 ubiquitination. Similar alterations were found in mesenteric VSMCs isolated from Ang II-infused mice. The effect of Ang II was emulated by 17-AAG that inhibits HSP90 interactions with client proteins. These results show that Ang II downregulates Kv7.4 by altering protein stability through a decrease of its interaction with HSP90. This leads to the recruitment of CHIP and Kv7.4 ubiquitination and degradation via the proteasome.

INTRODUCTION

Hypertension is associated with increased arterial contractility and resistance to receptor-mediated vasodilators. Kv7 channels (Kv7.1 – Kv7.5) are voltage-gated potassium (K+) channels encoded by KCNQ genes that regulate the contractile state of vascular smooth muscle at rest and contribute markedly to receptor-mediated vasorelaxations\(^1\). Arterial smooth muscle cells express Kv7.1, Kv7.4 and Kv7.5, with negligible Kv7.2 and Kv7.3 levels\(^3\), and blockers of these channels such as XE991 or linopirdine can contract most arteries or enhance vasoconstrictor responses\(^4\)-\(^6\). Conversely, agents that enhance Kv7 activity are effective vasorelaxants\(^4\)-\(^7\). In addition, Kv7 blockers, as well as knockdown of Kv7.4 impairs vasorelaxations produced by receptor agonists in various arteries\(^2\),\(^8\),\(^9\). Notably, many receptor-mediated vasorelaxations are impaired in arteries from hypertensive animals, and any remaining relaxation is no longer sensitive to Kv7 blockade\(^8\),\(^10\). The functional impairment is linked to a reduction of Kv7.4 protein abundance in renal, mesenteric and coronary arteries from hypertensive animals, which is not correlated with a reduction in gene transcript (KCNQ4), suggesting the involvement of post transcriptional mechanisms. Whilst some molecular determinants of the pathological changes in Kv7 channel expression occurring in the vasculature during hypertension have started to be unveiled\(^11\), the mechanisms that dictate the membrane abundance of Kv7.4 channels in smooth muscle are yet to be fully elucidated. K+ channel trafficking can be regulated by several processes, such as the protein internalization/endosomal recycling pathway\(^12\), and altered protein folding via changes in the interaction with molecular chaperones such as Heat Shock Proteins (HSPs)\(^13\). Here, we aim to uncover the processes governing the handling of Kv7.4 in vascular smooth muscle following treatment with Angiotensin II (Ang II), a molecule strongly associated with cardiovascular
dysfunction, to gain insight into the processes that control $K_v 7.4$ membrane abundance during hypertension.

**METHODS**

Detailed methods are available in the Online Supplement (http://hyper.ahajournals.org). The authors declare that all supporting data are available within the article (and its online supplementary files).

Animals

All experiments were performed in accordance with the UK Animals (Scientific Procedures) Act (1986) and were approved by the local ethics committees (St George’s Animal Welfare Committee, Barts and The London School of Medicine, University of Reading Animal Welfare and Ethical Review Board). 10-12 weeks-old male Wistar rats (Charles River, U.K.) and C57BL/6J mice (12-18 weeks of age) were killed by cervical dislocation. Animals were housed in a climatically controlled environment, on a 12h light/dark cycle, with free access to water and standard food ad libitum.

Statistical analysis

All data are expressed as mean ± s.e.m. One- or two-way ANOVA test followed by a Dunnett’s or Tukey’s multiple comparisons test, and Student’s t-test (paired or unpaired) were used to determine statistical significance between groups, according to the different experiments. Differences were considered statistically significant when $p<0.05$.

**RESULTS**

*Effects of Ang II on $K_v 7.4$ levels and function*
We first investigated the effects of Ang II on gross Kv7.4 levels in protein lysates from whole mesenteric arteries. Western blot experiments showed that 100nmol/L Ang II reduced Kv7.4 protein levels by ~50% after 1h compared to control vessels, by ~70% after 3h, and by ~80% after 7h treatment (Fig 1A). Incubation with Ang II did not reduce KCNQ4 mRNA levels even after 7h (Fig 1B), suggesting a post-transcriptional mechanism. Similar results were also observed in rat aorta (Fig S1A-B, http://hyper.ahajournals.org). To circumvent any possible non-specific binding of the Kv7.4 antibody we investigated the effects of Ang II treatment on a human smooth muscle cell line (SGVSM-9) transfected with EGFP-tagged Kv7.4, using an anti-GFP antibody. In SGVSM-9 cells transfected with EGFP-Kv7.4, in-cell western blot experiments showed that treatment for 1h with 100nmol/L Ang II induced a ~20% decrease in EGFP-Kv7.4 with respect to control cells (Fig 1C). Moreover, in CHO cells expressing the angiotensin II receptor type 1 (AT1R) and EGFP-Kv7.4, incubation of 100nmol/L Ang II for 1h decreased EGFP-Kv7.4 protein expression by ~30%, as measured by Western blot (Fig S1C, http://hyper.ahajournals.org).

We then evaluated the effects of Ang II on Kv7 function. Whole cell K^+ currents were recorded from isolated mesenteric artery myocytes and the Kv7 current was identified as the component sensitive to the selective blocker XE991 (1µmol/L) (Fig S2A, http://hyper.ahajournals.org). Incubation of 100nmol/L Ang II for 3h decreased the amplitude of XE991-sensitive current by about 60% (Fig 1D). ML213 is an activator of Kv7.2, Kv7.4 and Kv7.5 channels that has been characterized in several smooth muscles, including VSMCs from mesenteric arteries. In sharp microelectrode studies on whole mesenteric arteries ML213 hyperpolarized the membrane potential by approximately 17mV; a subsequent application of the K_ATP channel activator levocromakalin (10µmol/L) further increased membrane resting potential (Fig 1E and Fig S2B, http://hyper.ahajournals.org, control). Treatment with Ang II for 2h blunted ML213-induced hyperpolarization (increase of membrane potential by ~2mV) but did not affect the membrane
hyperpolarization caused by levcromakalin (Fig 1E and Fig S2B, http://hyper.ahajournals.org, Ang II). ML213-induced relaxation of pre-contracted mesenteric arteries is abolished by the Kv7 blockers XE991 (Fig S3, http://hyper.ahajournals.org) and linopirdine14. Incubation of mesenteric arteries with Ang II impaired the relaxation of pre-contracted mesenteric arteries produced by ML213 (Fig 1F and S2D, Fig S3, http://hyper.ahajournals.org), consistent with the loss of Kv7.4 function.

Effects on Ang II on Kv7.4 subcellular distribution

Kv7.4 subunits consistently show a clear and abundant peripheral distribution, following the shape of the cell membrane of the VSMC, whilst Kv7.1 was mainly intracellular and Kv7.5 signal was altogether less apparent and only occasionally localized at the plasma membrane (Fig S3, http://hyper.ahajournals.org). The Kv7.4 staining overlapped with the signal of the plasma membrane marker wheat germ agglutinin in control conditions (WGA, Fig. 2A). Treatment with 100nmol/L Ang II (3h) reduced the membrane localization of Kv7.4 concomitant with a decrease in the global level of Kv7.4 (Fig 2A). Fluorescence-intensity profiles along cross-sections of VSMCs showed that in control cells the Kv7.4 signal was higher in the membrane than cytosol (membrane:cytoplasm ratio 1.57±0.12), while in Ang II treated cells Kv7.4 fluorescence was similar between the two regions (membrane:cytoplasm ratio 0.88±0.10) (Fig 2B).

Role of endosomal and proteosomal pathways in Ang II-mediated Kv7.4 degradation

To gain insight about the cellular mechanisms that mediated the shift in Kv7.4 localization and reduction in total protein levels, mesenteric arteries were incubated with the endosome inhibitor dynasore or the proteasome inhibitor MG132 in presence or absence of Ang II. In Western blot experiments co-incubation of dynasore (DYN), used at concentrations (100μmol/L) shown to
be effective in previous studies\textsuperscript{15}, did not fully prevent the reduction of $K_v7.4$ produced by 3h incubation with Ang II (Fig. 2C). Conversely, MG132 (20 $\mu$mol/L) fully prevented the Ang II-induced reduction of $K_v7.4$ (Fig. 2C). MG132 also counteracted the impairment of ML213-induced relaxation of mesenteric arteries by Ang II in myography experiments (Fig 2D).

\textit{Role of oxidative stress in Ang II-induced $K_v7.4$ degradation}

Ang II is known to increase oxidative stress\textsuperscript{16} which induces proteasome-mediated protein degradation\textsuperscript{17}. We therefore evaluated whether the observed increase of $K_v7.4$ protein degradation induced by Ang II was mediated by oxidative stress. In VSMCs, treatment with Ang II for 30min increased the production of reactive oxygen species (ROS) measured by the fluorescence dye ROS Deep Red (by ~50\% compared to time-matched control), similarly to that caused by 1mmol/L H$_2$O$_2$ (increase by ~70\%, Fig 3A). In contrast, longer incubation (3h) with Ang II did not significantly enhance ROS levels with respect to time-matched control, whereas H$_2$O$_2$ was still able to increase ROS levels (by ~40\%, (Fig 3A). The ROS scavenger N-Acetyl-L-Cysteine (NAC, 1mmol/L) counteracted Ang II-induced ROS production (Fig S5, \url{http://hyper.ahajournals.org}), but did not prevent either $K_v7.4$ protein down-regulation (Fig 3B) or the impairment of ML213-induced relaxation in mesenteric arteries when co-incubated with Ang II (Fig 3C).

\textit{Role of HSPs in Ang II-mediated $K_v7.4$ degradation}

HSP70/90 machinery is abundantly expressed in eukaryotic cells, and is a key regulator of protein homeostasis in both physiologic and pathologic conditions\textsuperscript{18}. Moreover, HSP70/90 interact with $K_v7.4$ in heterologous-expression systems\textsuperscript{19}. Neither HSP70 nor HSP90 transcript/protein levels changed in Ang II-treated mesenteric arteries compared to control vessels (Fig S6, \url{http://hyper.ahajournals.org}). Therefore, we investigated whether Ang II-
induced downregulation of Kv7.4 was mediated by an altered interaction with HSPs using Proximity Ligation Assay (PLA). No significant differences in the number of interactions between Kv7.4 and HSP70 were observed in isolated VSMCs treated with Ang II when compared to controls (Fig 4A). In contrast, a significant reduction (by ~40%) in Kv7.4:HSP90 interactions was detected in VSMCs upon incubation with Ang II (Fig 4B). HSP70/90 machinery is linked to the proteasome system via the co-chaperone and E3 ubiquitin-ligase CHIP (C-terminus of Hsp70-Interacting Protein). Incubation of VSMCs with Ang II enhanced the interaction of Kv7.4 with CHIP by ~30% (Fig 4C), and increased the number of ubiquitin molecules interacting with Kv7.4 by ~65% when compared to control (Fig 4D). These data suggested that Ang II reduced Kv7.4:HSP90 interactions thus enhancing protein ubiquitination via an increased interaction of Kv7.4:HSP70 complex with CHIP. To corroborate this, we studied the effect of 17-AAG (17-Demethoxy-17-(2-propenylamino) geldanamycin), a geldanamycin-analog which inhibits HSP90 function, on total Kv7.4 protein levels. Incubation of mesenteric arteries with 1µmol/L 17-AAG caused a reduction of Kv7.4 protein by ~60% (Fig 5A), increased the number of interactions between Kv7.4 and CHIP (Fig 5B), and the number of ubiquitin molecules interacting with Kv7.4 (Fig 5C).

Role of HSPs-CHIP-ubiquitin system in Kv7.4 degradation in vivo

Since Kv7.4 protein is down-regulated in Ang II-infused mice, we investigated whether the observed alterations of HSPs-CHIP-ubiquitin system could be detected in the same in vivo model of prolonged exposure to Ang II. PLAs showed that the number of interactions of Kv7.4 with HSP70 in VSMCs isolated from mesenteric arteries of Ang II-infused mice was not significantly different from those isolated from saline-infused mice (Fig 6A), whereas a significant decrease in the number of Kv7.4:HSP90 interactions was observed in VSMCs from Ang II- with respect to saline-infused mice (Fig 6B). Moreover, an increased interaction of

HSP70/90 machinery is linked to the proteasome system via the co-chaperone and E3 ubiquitin-ligase CHIP (C-terminus of Hsp70-Interacting Protein). In incubation of VSMCs with Ang II enhanced the interaction of Kv7.4 with CHIP by ~30% (Fig 4C), and increased the number of ubiquitin molecules interacting with Kv7.4 by ~65% when compared to control (Fig 4D). These data suggested that Ang II reduced Kv7.4:HSP90 interactions thus enhancing protein ubiquitination via an increased interaction of Kv7.4:HSP70 complex with CHIP. To corroborate this, we studied the effect of 17-AAG (17-Demethoxy-17-(2-propenylamino) geldanamycin), a geldanamycin-analog which inhibits HSP90 function, on total Kv7.4 protein levels. Incubation of mesenteric arteries with 1µmol/L 17-AAG caused a reduction of Kv7.4 protein by ~60% (Fig 5A), increased the number of interactions between Kv7.4 and CHIP (Fig 5B), and the number of ubiquitin molecules interacting with Kv7.4 (Fig 5C).

Role of HSPs-CHIP-ubiquitin system in Kv7.4 degradation in vivo

Since Kv7.4 protein is down-regulated in Ang II-infused mice, we investigated whether the observed alterations of HSPs-CHIP-ubiquitin system could be detected in the same in vivo model of prolonged exposure to Ang II. PLAs showed that the number of interactions of Kv7.4 with HSP70 in VSMCs isolated from mesenteric arteries of Ang II-infused mice was not significantly different from those isolated from saline-infused mice (Fig 6A), whereas a significant decrease in the number of Kv7.4:HSP90 interactions was observed in VSMCs from Ang II- with respect to saline-infused mice (Fig 6B). Moreover, an increased interaction of
Kv7.4 with CHIP (Fig 6C) and ubiquitin (Fig 6D) was detected in VSMCs from Ang II-mice when compared to control groups.

**DISCUSSION**

*Ang II reduces Kv7 expression and function via increased proteasome-mediated degradation*

In this study, we present novel and detailed mechanistic information showing how Ang II, a key mediator of the pathological changes occurring in vascular disease\(^{16}\), modulates Kv7.4 channel expression, which is down-regulated in hypertension\(^7\). Ang II has been demonstrated to acutely (up to 25 min) suppress the XE991-sensitive Kv current in mesenteric VSMCs\(^{20}\), but no insight regarding the molecular mechanisms involved was provided, and the effects of longer exposure of Ang II on Kv7 expression and function were not studied. Our data show that treatment with Ang II (1-7h) reduced the expression of Kv7.4 protein, decreased the amplitude of voltage-dependent currents sensitive to the pan-Kv7 channels blocker XE991 in VSMCs, blunted the hyperpolarization of the VSMCs membrane induced by the Kv7 activator ML213, and impaired the vasorelaxant effects induced by the same drug in whole mesenteric arteries. In contrast, Ang II did not affect the ability of the K\(_{ATP}\) channel activator levocromakalin to hyperpolarize VSMCs. ML213 effects in smooth muscle are abolished by Kv7 blockers like XE991 (Fig S3, http://hyper.ahajournals.org) or linopirdine\(^{14}\), strongly suggesting the involvement of Kv7 channels in ML213-induced arterial relaxation. ML213 has been reported to be more specific for channels formed by Kv7.2 (whose expression in VSMCs is negligible\(^3\)) or Kv7.4 subunits\(^{21}\), but one study suggested that it also enhances the current mediated by Kv7.5\(^{22}\), which contributes with Kv7.4 to the formation of the mature channel in the vasculature\(^1,23\). Due to the lack of Kv7 subunit-specific blockers, we could not rule out the involvement of Kv7.5 in ML213-induced relaxation. However, our immunofluorescence data (Fig S4, http://hyper.ahajournals.org) together with previous evidence\(^2,8,9,23\) infer that the
reduction of vasorelaxant effects of ML213 prompted by Ang II was mediated by decreased K\textsubscript{v}7.4 levels in VSMCs. Interestingly, ML213 still produced some relaxation in Ang II-treated arteries even though its ability to hyperpolarize was largely (but not entirely) lost by incubation with Ang II. A previous study revealed that 1µM ML213 produced considerable relaxation of pre-contracted arteries without marked membrane hyperpolarization\textsuperscript{14}. This apparent discrepancy in electro-mechanical coupling probably reflects the differences in experimental conditions, as isometric tension studies involved a pre-contracted and therefore depolarized artery compared to the microelectrode recordings performed on unstimulated arteries. Like other K\textsubscript{v}7.2-7.5 activators ML213 works through stabilization of the open configuration that will be more apparent under depolarized conditions. However, further investigation regarding the role of K\textsubscript{v}7 channels in regulating the electro-mechanical coupling in VSMCs is required.

K\textsubscript{v}7.4 down-regulation was also confirmed in clonal cells expressing heterologous K\textsubscript{v}7.4 channels, and was not accompanied by a reduction in mRNA levels, indicating that Ang II reduced K\textsubscript{v}7.4 by post-transcriptional mechanisms. Modulation of protein trafficking, recycling and degradation has a considerable impact on K\textsuperscript{+} channels expression and function\textsuperscript{24} and dysregulation of recycling/degradation pathways has been linked to channelopathies such as hereditary arrhythmias or cystic fibrosis\textsuperscript{24}. Our findings reveal that degradation of K\textsubscript{v}7.4 protein by Ang II treatment and the subsequent functional impairment of K\textsubscript{v}7-dependant vasorelaxation was prevented by proteasome inhibition. Ang II has been shown to induce proteasome degradation of large conductance calcium activated BK channels via increased endosome-mediated internalization in VSMCs, and Kv11.1 (ERG) channels in over-expression systems\textsuperscript{15,25}. Interestingly, in contrast to the above studies where Ang II effects were noticeable after prolonged treatment (7-24h), we observed downregulation and altered subcellular distribution of K\textsubscript{v}7.4 after as little as 1h. Moreover, the lack of effect of dynasore in fully restoring K\textsubscript{v}7.4 protein levels suggest that the endosomal pathway does not play a primary role
in Ang II-induced Kv7.4 down-regulation in contrast to BKCa channels\textsuperscript{15}. Previous studies have established that Ang II causes oxidative stress in target cells\textsuperscript{16}, and that the increased ROS levels activate the ubiquitin-proteasome system, as a protective mechanism to prevent the accumulation/aggregation of oxidized proteins\textsuperscript{17}. In our experiments, Ang II caused a rapid increase in ROS levels (30min) which did not persist with longer exposure (3h), and the ROS scavenger N-Acetyl-L-Cysteine did not prevent the down-regulation of Kv7.4 levels and function prompted by Ang II. Although we cannot exclude the possibility that sustained oxidative stress reduces Kv7.4 levels, our data suggest that the early burst of ROS production induced by Ang II was not sufficient to alter Kv7.4 abundance, and that the activation of the proteasome system triggered by oxidative stress was not the main mechanisms involved in Ang II-induced downregulation of Kv7.4.

\textbf{Ang II-induced decrease of Kv7.4-HSP90 interaction promotes the ubiquitination of Kv7.4}

Ang II affects protein folding in hypertensive mice\textsuperscript{26}, regulates the activity of HSPs, which mediate some maladaptive responses occurring in hypertension\textsuperscript{27}, and also regulate ion channel folding. HSP90 in particular, plays a pivotal role in the folding of the cystic fibrosis transmembrane conductance regulator (CFTR), the CIC-2 chloride channel\textsuperscript{28}, HERG channel\textsuperscript{13} and the K\textsubscript{ATP} potassium channel\textsuperscript{29}. Moreover, enhancement of the HERG:HSP90 interaction is responsible for the increased membrane trafficking induced by estradiol\textsuperscript{30}. Reduced binding of HSP90 decreases the interaction of client proteins with the HSP40-HSP70-HOP chaperone pathway that promotes forward trafficking, and increases interaction with HSP70-ubiquitin ligase CHIP complexes, which lead to proteasome-mediated degradation\textsuperscript{31}. Our data reveal that the molecular chaperones HSP70/90 interact with Kv7.4 in native VSMCs, and that Ang II treatment selectively reduced the interaction of Kv7.4 with HSP90 in this physiological environment. In heterologous expression systems, modulating HSP90 isoforms levels either by overexpression or silencing strategies revealed a differential role in Kv7.4 maturation of the
two major HSP90 isoforms, namely α and β, with β-isoform promoting protein folding, and α-isoform enhancing CHIP-mediated proteasomal degradation\textsuperscript{32}. Although some distinctive features exist, HSP90 isoforms exert similar actions, with many functions being characteristic of both isoforms and only associated more frequently to one of them\textsuperscript{33}. Moreover, their expression is differentially regulated, with a constitutive form (HSP90β) and an inducible one (HSP90α). Although we did not investigate the contribution of α- or β-isoform, in our experiments we did not observe any change in HSP90 levels, suggesting that HSP90 expression was not modified by Ang II incubation, and that a different mechanism was responsible for the alteration in Kv7.4:HSP90 binding. Covalent modifications, including phosphorylation, acetylation and nitrosylation, influence the activity of HSP90 and consequently the maturation of selected clients. Phosphorylation and acetylation slow down HSP90 activity, resulting in a reduced maturation of client proteins\textsuperscript{34,35}. Therefore, Ang II might activate different pathways ultimately altering HSP90 and/or Kv7.4, modifying their ability to interact. Irrespective of the molecular mechanism, the ultimate effect was an increased interaction of Kv7.4 with CHIP and an enhanced ubiquitination of Kv7.4 as determined by PLA. This hypothesis was corroborated by studies with 17-AAG, a pharmacological inhibitor of HSP90, that in our experiments reproduced the effects of Ang II in terms of Kv7.4 down-regulation, interaction with CHIP and ubiquitination. Our results are in line with previous evidence showing that pharmacological inhibition of HSP90 induces rapid degradation of client proteins through the ubiquitin-proteasome pathway\textsuperscript{13,36}.

**PERSPECTIVES**

We show for the first time in vascular smooth muscle that Ang II enhances Kv7.4 degradation via the ubiquitin-proteasome system, through a reduced interaction with HSP90. The specific pathway(s) activated by Ang II, as well as the possible molecular modifications occurring in all the interactors (including additional co-chaperones) will need to be further investigated.
Indeed, Ang II can activate diverse intracellular pathways, including non G-protein signaling, and modulate several processes, such as inflammation\textsuperscript{16}, which might in turn regulate HSPs activity and therefore protein stability and degradation. However, the present study has identified a novel and dynamic regulation of Kv.7.4 that impacts considerably on vascular physiology. Noticeably, we showed that these alterations also occur \textit{in vivo} after chronic exposure to Ang II, a well-known model of hypertension where Kv.7.4 expression and function is reduced\textsuperscript{7}, suggesting that the observed reduction of Kv.7.4 protein stability and enhanced degradation play a role also in the pathological changes occurring in hypertension. Since modulators of HSP90 function are being developed therapeutically\textsuperscript{37-39}, these data provide a possible new therapeutic strategy for the treatment of hypertension.

**ACKNOWLEDGEMENTS**

We thank Prof. Guy Whitley (St George’s, University of London) for providing SGVSM-9 cells, and Prof. Riccardo Olcese (University of California Los Angeles) for sharing pcDNA-AT1R plasmid.

REFERENCES

NOVELTY AND SIGNIFICANCE

**What is new.** We showed that Ang II decreases the expression and function of Kv7.4 potassium channels in vascular smooth muscle cells by reducing its interaction with chaperone protein HSP90 and altering protein stability.

**What is relevant.** Kv7.4 is an important mediator of arterial relaxation and is down-regulated in hypertension, a condition where Ang II is dysregulated. Increasing HSP90 activity might represent a new strategy to treat hypertension.

**Summary.** Ang II down-regulates Kv7.4 by disrupting its interaction with HSP90, which lead to the recruitment of the ubiquitin-ligase CHIP and the subsequent protein degradation via the proteasome.

(A) Immunofluorescence experiments showing Kv7.4 (red pseudocolor) in absence (CTL) or in presence (Ang II) of 100nmol/L Ang II. Staining of the plasma membrane marker wheat germ agglutinin (WGA, green pseudocolor) and nuclear marker DAPI (blue pseudocolor) are also shown. Scale bar: 5µm. (B) Top: fluorescence intensity profiles for Kv7.4 (red) and WGA (green) along the yellow line drawn in the pictures, expressed as Arbitrary Units (AU), in control (CTL) or Ang II-treated VSMCs. Regions where WGA intensity was <5AU were considered as cytosol (C), while portions where intensity was above the threshold were identified as plasma membrane (M). Bottom: bar graph showing the ratio between the average fluorescence intensities in the plasma-membrane and cytosol in VSMCs. For each cell, the mean of the ratios obtained along three random lines was calculated. n=15 cells per experimental point, obtained from 3-4 rats in 3-4 sessions. ***=p<0.001 (Student’s t-test). (C) Top: representative western blot showing Kv7.4 and β-actin proteins in mesenteric arteries after incubation for 3h with different combinations of 100nmol/L Ang II, 100μmol/L dynasore (DYN), and 20μmol/L MG132, as indicated. Bottom: quantification of western blot experiments. Normalized Kv7.4 intensities are expressed as percentage of control. n=6: **=p<0.01, ns=non significant (one-way ANOVA). (D) Isometric tension recordings in mesenteric arteries incubated for 3 hours in control conditions or with 100nmol/L Ang II in absence of presence of 20μmol/L MG132. The graph shows the relaxation to ML213 in arteries pre-contracted with 300nmol/L U46619. Data are expressed as percentage of the maximum contraction to U46619. n=4-6. *=p<0.05: **=p<0.01: ****=p<0.0001 (two-way ANOVA).

Fig. 3. Role of oxidative stress in the downregulation of Kv7.4 induced by Ang II. (A) Left: representative images showing the fluorescence of the ROS-sensitive dye ROS Deep Red in mesenteric VSMCs after incubation for 30 min (upper panels) or 3 hours (lower panels) in...
control medium (CTL) or in presence of 100nmol/L Ang II or 1mmol/L H$_2$O$_2$. Right: quantification of ROS Deep Red fluorescence intensity in VSMCs, expressed as Arbitrary Units (AU). n=35-48 cells obtained from 4-5 rats per experimental point in 4-5 sessions. *=p<0.05, ns=not significant (one-way ANOVA). (B) The inset shows a representative western blot of K$_v$7.4 and β-actin proteins in mesenteric arteries after incubation for 3 hours with different combination of 100nmol/L Ang II and 1mmol/L of N-Acetyl-L-Cysteine (NAC), as indicated. The bar graph shows the quantification of western blot experiments. n=6. *=p<0.05 (one-way ANOVA). (C) Isometric tension recordings in mesenteric arteries incubated for 3 hours in control condition or with 100nmol/L Ang II in absence of presence of 1mmol/L NAC. The graph shows the relaxation to ML213 in arteries pre-contracted with 1μmol/L U46619. Data are expressed as percentage of the maximum contraction to U46619. n=6. **=p<0.01, ***=p<0.001 ****=p<0.0001 (two-way ANOVA).

Fig. 4. Effects of Ang II on K$_v$7.4 interaction with Heat Shock Proteins and ubiquitin. Proximity Ligation Assay showing the interaction of K$_v$7.4 with HSP70 (A), HSP90 (B), CHIP (C), and ubiquitin (D) in mesenteric artery myocytes. Representative fluorescence and bright field (insets) confocal mid-cell xy sections of mesenteric VSMCs in absence (CTL) or presence (Ang II) of 100nmol/L Ang II are shown for each panel. Red puncta indicate target proteins are in close proximity (<40 nm). Bar graphs show the quantification of the mean number of PLA signals per mid-cell xy section. n=17-40 cells from 3-4 rats per experimental point in 3-4 sessions. *=p<0.05, **=p<0.001, ****=p<0.0001 (Student’s t-test). Nuclei (DAPI staining, blue) are also shown. Scale bar: 5µm.

Fig. 5. Effects of HSP90 inhibition on K$_v$7.4 levels, interaction with CHIP, and ubiquitination. (A) Left: representative western blot showing K$_v$7.4 and β-actin in mesenteric arteries incubated with DMSO (CTL) or 1μmol/L 17-AAG. Right: quantification of western blot experiments. n=5. *=p<0.05 (Student’s t-test). (B-C) Proximity Ligation Assay showing
the interaction of Kv7.4 with CHIP (B) and ubiquitin (C) in mesenteric artery myocytes. Representative fluorescence and bright field (insets) confocal mid-cell xy sections of mesenteric artery myocytes incubated with DMSO (CTL) or 1μmol/L 17-AAG are shown for both panels. Red puncta indicate target proteins are in close proximity (<40nm). Nuclei (DAPI staining) are shown in blue pseudocolor. Scale bar: 5μm. Bar graphs show the quantification of the mean number of PLA signals per mid-cell xy section. n=24-44 cells from 3-4 rats per experimental point in 3-4 sessions. *=p<0.05, ****=p<0.0001 (Student’s t-test).

Fig. 6. Kv7.4 interaction with Heat Shock Proteins, CHIP and ubiquitin in Ang II-infused mice. Proximity Ligation Assay showing the interaction of Kv7.4 with HSP70 (A), HSP90 (B), CHIP (C), and ubiquitin (D) in mesenteric artery myocytes obtained from mice infused for 28 days with saline solution or Ang II. Representative fluorescence and bright field (insets) confocal mid-cell xy sections of mesenteric VSMCs from saline- or Ang II-infused mice are shown for each panel. Red puncta indicate target proteins are in close proximity (<40 nm). Bar graphs show the quantification of the mean number of PLA signals per mid-cell xy section. n=35-40 cells from 4 mice per experimental group. *=p<0.05, **=p<0.01, ****=p<0.0001 (Student’s t-test). Nuclei (DAPI staining, blue) are also shown. Scale bar: 5μm.
