ABSTRACT:

Terrestrial mammals have evolved various foot postures: flat-footed (plantigrady), tip-toed (digitigrady), and hooved (unguligrady) postures. Although the importance of foot posture on ecology and body size of mammalian species has been widely recognized, its evolutionary trajectory and influence on body size evolution across mammalian phylogeny remain untested. Taking a Bayesian phylogenetic approach combined with a comprehensive new data set of foot postures in 880 extant mammalian species, we investigated the evolutionary history of foot postures and rates of body size evolution, within the same posture and at transitions between postures. Our results show that the common ancestor of mammals was plantigrade and transitions predominantly occurred only between plantigrady and digitigrady, and between digitigrady and unguligrady – this is the first time such a directional evolution has been statistically determined from data. At the transitions between plantigrady and digitigrady, and between digitigrady and unguligrady, rates of body size evolution are significantly elevated leading to the larger body masses of digitigrade species (~1 kg) and unguligrade species (~78 kg) compared to their respective ancestral postures (plantigrady (~0.75 kg) and digitigrady). Our results demonstrate the importance of foot postures on mammalian body size evolution and have implications for mammalian body size increase through time. In addition, we highlight a way forward for future studies that seek to integrate morphofunctional and macroevolutionary approaches.

SIGNIFICANCE STATEMENT:

Terrestrial mammals have evolved diverse foot postures, contributing to their ecological success. Yet, how postures evolved and how they affected body size evolution remain largely unknown. Here, for the first time we statistically reconstruct the paths and trajectories in foot posture evolution and explicitly tested the effects of posture on body size evolution, using phylogenetic Bayesian approaches. We found that upright foot postures evolved in a directional manner, from flat-footed ancestors, to tip-toed, and then to hooved descendants. Furthermore, transitions to different foot postures are associated with increases in rates of body size evolution, rapidly leading to larger descendants, demonstrating how transitions between foot postures have had profound influences on mammalian body size evolution.

Mammals have come to occupy a wide range of ecological niches, they span six orders of magnitude in body size (1), and inhabit most terrestrial environments. Adapting to diverse environments, mammals have evolved various foot postures that can be largely summarized into: plantigrady (P; walking on the whole foot, e.g., mice, rats, squirrels and humans); digitigrady (D; walking on toes, e.g., cats and dogs); and unguligrady (U; walking on hooved tip-toes, e.g., deer and horses) (2). These foot postures are tightly associated with the ecology of mammals – cursorial and graviportal mammals are digitigrade or unguligrade, whereas fossorial, arboreal, ambulatory or saltatorial (2, 3) mammals are plantigrade (though (2) considers salutatory as a distinct ecomorph). Ecological adaptations associated with each posture are most prominent in the morphology and biomechanics of the autopod (ulna+radius/tibia+fibula) and zeugopod (wrist+finger/ankle+toe), offering different advantages in various aspects of species biology (4-8).

In spite of the evolutionary importance of autopod and zeugopod adaptations that are associated with foot postures, precisely how the different postures evolved across the mammalian tree of life remains poorly understood. Biomechanical predictions along with the fossil record provide us with some snapshots of how a few extinct species moved, which hint at how foot postures evolved (9-14). However, current hypotheses of locomotor evolution are yet to be tested statistically in an evolutionary context using empirical foot posture data covering a broad taxonomic sample.

Phylogenetic comparative methods are powerful tools with which one can statistically infer past events through Earth history while characterising large-scale macro-evolutionary processes (15). Accounting for and using shared ancestry as described by phylogeny is crucial in understanding evolution because apparent similarities/differences could simply owe to interrelationships (16, 17).
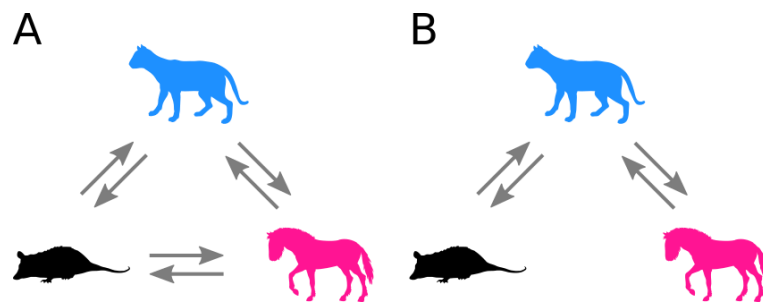

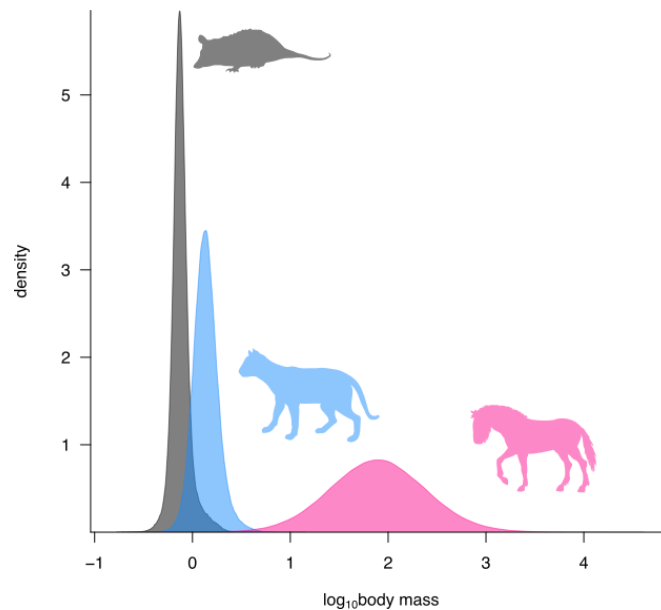

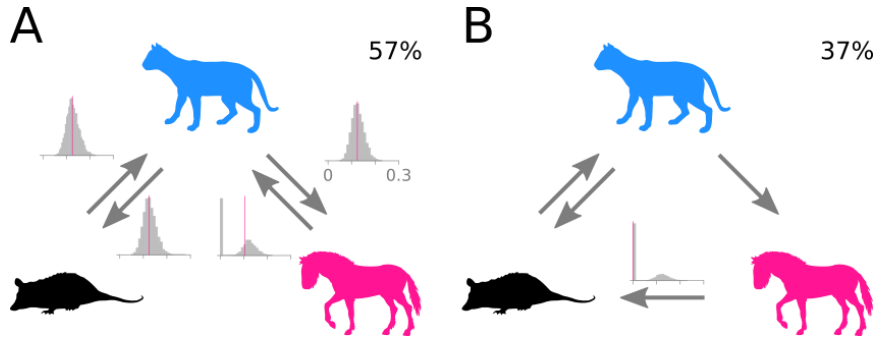

Figure 1

If we assume transitions between each pair of foot postures are equally probable, the expectation (the null hypothesis, H_0) would be that transitions amongst foot postures would have occurred in any direction between any pair (Fig. 1A). Hints from the fragmentary fossil record indicate that the null hypothesis may not be true, especially with regards to how unguligrady arose (9, 10, 12, 13) (Fig. 1B). To gain a more complete understanding of the evolution of foot postures we use a Bayesian phylogenetic approach (16, 18) to infer patterns of transitions amongst foot postures across the mammal tree of life using a comprehensive new data set collected for extant species. Our approach does not explicitly make any *a priori* assumptions or constraints on patterns of transitions amongst foot postures.

Foot postures have been suggested to influence the evolution of body sizes (19). With this in mind, understanding how foot postures evolve may provide us with a better understanding of how body size evolved in mammals. Lovegrove and Haines (19) demonstrated that the distribution of mammalian body sizes may be explained by multiple distributions – with each sub-distribution tied to a different foot posture (P, D, and U) – sufficiently better than by a single distribution, classically regarded as being right-skewed (Fig. S1)(20-23). This notion fits with a previous empirical observation that the mammalian

species body size distribution actually deviates from the classic single right skewed distribution mainly owing to an under-abundance of species around 1kg and over-abundance of species around 300 kg (24). Since different locomotor modes are associated with differences in body sizes (phylogenetic median body mass: plantigrady, 0.75 kg; digitigrady, 1.35 kg; and unguligrady, 78.1 kg) (Fig 2), it follows that transitions from one posture to another may be accompanied by rapid changes in body size – these could be in line with Simpson's well know notion of "*quantum evolution*" (25). Thus, we would expect accelerated rates of body size evolution along branches associated with transitions from one foot posture to another, particularly transitions into unguligrady given the extraordinarily larger average body sizes of unguligrade taxa compared to taxa of other foot postures (Fig 2).

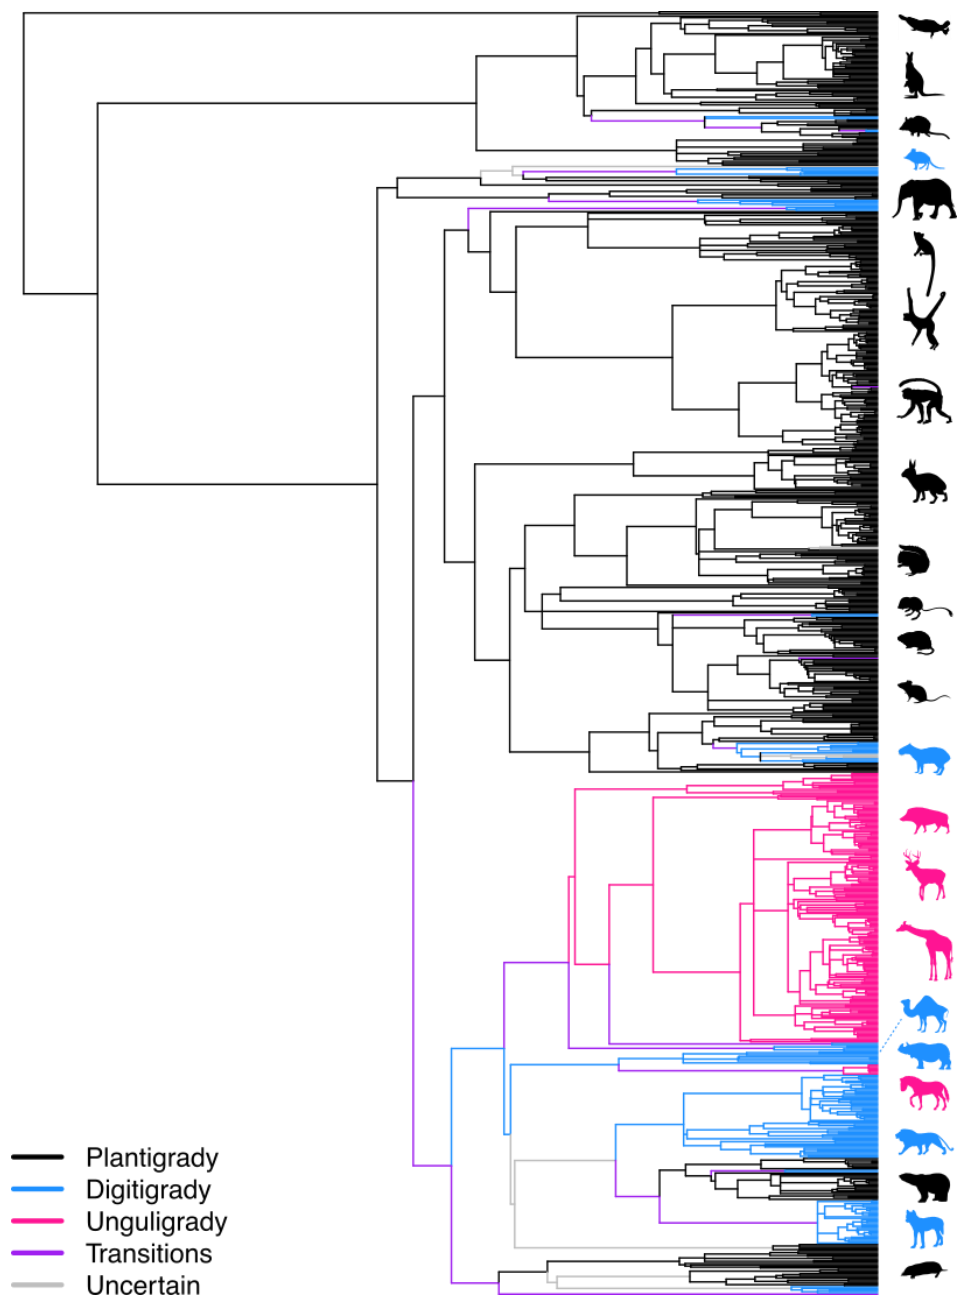

*Figure 2*

Figure 3

RESULTS AND DISCUSSION

We inferred transition rates amongst the different foot postures on a newly collected dataset in 880 species of extant mammals (See Methods; SI), and a comprehensive species-level time-calibrated phylogeny (26), using a reversible-jump (RJ) continuous time Markov model (16). We find strong support for the notion that the ancestral mammal was plantigrady P (probability of state P, P_P=1). The dominant pattern that we reveal is that transition rates (q_{ij} where i and j are two states) between P and D (q_{PD} and q_{DP}), and between D and U (q_{DU} and q_{UD}) are non-zero, with transition rates q_{PU} and q_{UP} being zero in the majority of the posterior sample (Fig. 3A), consistent with the fossil record (Fig. 1B)(2). This exact combination of non-zero transition rates (Fig. 3A) occurs as the predominant model in the posterior sample (57%) with the next most frequent model of transitions (37% of the posterior) having q_{UP} as a non-zero rate instead of q_{UD} (Fig. 3B).

On average, there is a significant difference in body masses amongst the different foot posture groups: digitigrade taxa are larger than plantigrade taxa, while unguligrade taxa are larger than digitigrade taxa (Fig 2). Thus, we hypothesise that transitions between foot postures would be associated with elevated rates in body size evolution compared to that within postures ($\sigma_T^2 > \sigma_b^2$ where σ_T^2 is the rate of evolution associated with transitional

7

branches while σ_b^2 is the background [within-posture] rate of evolution). In order to test whether rates of body size evolution differed between sets of branches along which transitions in foot posture occurred (Fig. 4, purple branches) with those that remained in the same posture (Fig. 4, black [P], blue [D] and pink [U] branches), we estimated separate rates of body size evolution for each partition of branches across the phylogenetic tree, where branches were partitioned according to differences in reconstructed nodal posture states (Fig. S2). That is, for each branch of the phylogenetic tree, we compared the states of the ancestral and descendant nodes using ancestral state reconstructions (ASR) resulting from the top multistate model described in the text (Fig. 3A). We took the single ASR with the highest probability (at $P_{ASR} > 0.67$ [2/3], which is double the probability that a state can be reconstructed by chance alone [1/3]; Fig 4). If the two states were identical (e.g., ancestor=D and descendant=D) then we would assign that branch to that specific posture (e.g., D) partition, but if they differed (e.g., ancestor=D and descendant=U), we would assign that branch to a transitional partition (Fig. S2). Branches for which posture states could not be determined – i.e., a single ASR for either ancestral or descendant nodes cannot be assigned at $P_{ASR} > 0.67$ – were partitioned as "uncertain". Separate rates σ_x^2 of body size evolution were estimated for each partition. Additionally, individual branches or monophyletic groups were allowed to vary in rate σ_v^2 (27) on top of the partitioned rates – minimising the effects of rare and exceptional rate shifts on partition-wise rate (σ_x^2) estimates.

Figure 4

Figure 5

We find that the rate of evolution of body size across transitions between foot postures (σ_T^2) are significantly higher than that within postures (σ_b^2; Fig 5; Fig. S4) – i.e., the proportion of the posterior in which differences between rates straddle 0 is less than 0.05 ($p_{MCMC} < 0.05$) (Table 1). Elevated rates indicate that the statistically significant differences in body masses between P and D and between D and U (Fig 2) were not attained gradually owing to the passage of time but through instances of elevated rates of evolution – transitional branches are associate with a 7-fold increase compared to rates associated with within-posture branches (Table 1).

That transitions between foot postures are associated with rate increases in body size evolution imply that morphological adaptations associated with changes in foot posture facilitate rapid changes in body size. For instance, upright foot postures are beneficial, if not necessary, for terrestrial animals of larger sizes and that with high-speed locomotion, as they can compensate for increasing stresses on musculoskeletal systems that are associated with higher body masses or strenuous activitites (4, 5, 7, 8). Upright foot postures have also

been suggested as being an energy-saving mechanism, with lower metabolic costs to locomotion compared to non-upright foot postures (7). Morphological adaptations associated with upright foot postures thus were most likely advantageous with regards to efficient locomotion and reduction in metabolic costs, potentially enabling a burst of evolution to larger body sizes associated with acquisitions of more upright foot postures (i.e., P→D, D→U). In addition, secondary digitigrady in graviportal taxa like rhinos (i.e., U→D) would allow body size increase by reducing planter pressure with thick foot pads.

On the other hand, strong selection for rapid changes in body size may necessitate transitions in foot postures. That is, it has been previously hypothesised that plantigrade mammals were restricted to small body sizes throughout the Cenozoic owing to predation pressures from large cursorial digitigrade predators, while digitigrade and unguligrade mammals were free to increase in size presumably owing to reduced predation pressures (28). Thus, it is possible that for a small plantigrade taxon to rapidly increase in size to evade predation pressures, which may necessitate transitions in foot postures for biomechanical and energetic reasons discussed above.

As correlation does not imply causation, it is impossible to ascertain whether transitions between foot postures drove size changes or the other way around. Future studies incorporating fossil taxa may shed light on this issue. However, what is discernible is the discontinuity of body size evolution across foot postures – i.e., bursts of rapid evolution between significantly different group means (Figs 2, 4). That there is an interval in mean body sizes between two foot postures which is associated with rapid bursts of evolution to get from one to the other is reminiscent of the classic hypothesis of "quantum" evolution across adaptive zones (25).

The discontinuity in size between plantigrade and non-plantigrade (digitigrade, unguligrade) tetrapods seems to have existed, prior to that observed in mammals, for more than 200 million years since the emergence of the first digitigrade tetrapod, Dinosauromorpha (29), and is globally observed among extant non-volant birds (29). Thus, it is possible that differences in foot postures have affected body size evolution universally throughout the evolutionary history of tetrapods – future collection of relevant autopod and zeugopod morphological data in a wide range of terrestrial tetrapods (living and extinct) and macroevolutionary statistical analyses (such as those conducted here) may shed light on this issue.

METHODS

Data collection. Foot postures of mammals were grouped into three categories: plantigrady (P), digitigrady (D), and unguligrady (U). Categorization was based on analyses of videos of walking animals obtained from online resources (e.g., http://www.arkive.org/; see SI). Videos were searched for all terrestrial mammalian species (i.e., excluding Chiroptera and aquatic species), for which corresponding body mass data are available in the PanTHERIA database (1). When suitable videos were unavailable for a species, that species was excluded from subsequent analyses. When videos were unavailable for species within Artiodactyla, Perissodactyla, Canidae, Felidae, and Hyaenidae, foot posture was determined from photographs, and when photographs were unavailable, they were omitted. The criterion for foot posture categorization is as follows. The stance of the animal at which they paused during locomotion – i.e., when all four zeugopods are in contact with the ground for a few seconds – was used for judging its foot posture. A species was categorized as P, if their tarso-metatarsal joint contacted the ground. If the tarso-metatarsal joints were clearly off

the ground, they were categorized as D, and if the metatarso-phalangeal joints were off the

ground, they were categorized as U. Graviportal species with elephantine feet, with thick

foot pads underneath the metatarso-phalangeal joints that contacted the ground, were

categorized as D, (rhinos, tapirs, hippos, camels), while elephants were categorized as P,

based on the distribution of their planter pressure (SI).

We used the Time Tree of Life (TTOL) (26) and pruned out the tips for which we do

not have posture data, resulting in 880 species (Table S1). We also tested the effects of tree

topology on our results using a tree with an alternate topology (SI).

Phylogenetic comparative methods. In order to estimate transition rates amongst

the different foot postures, we used the reversible-jump continuous time Markov model

(16) in BayesTraits (18), simultaneously reconstructing ancestral states for each node in the

tree. We ran three independent Markov Chain Monte Carlo (MCMC) chains for 10^8

iterations sampling every 10^5 iterations after burning in for 10^7 iterations. We used an

exponential (0, 1) hyper-prior. We did not set any restrictions on transitions *a priori* for the

initial model. We computed marginal log likelihoods using stepping stone sampling (30) over

1,000 stones at 250,000 iterations per stone.

In order to test whether rates of body size evolution differed amongst branches

along which transitions in foot posture occurred, we estimated separate rates of body size

evolution for each partition of branches across the phylogenetic tree, where branches were

partitioned according to differences in reconstructed nodal posture states (Fig. S2). That is,

for each branch of the phylogenetic tree, we compared the states of the ancestral and

descendant nodes using ASR resulting from the top multistate model described in the text

(Fig. 3A). We took the single ASR with the highest probability (at $P_{ASR} > 0.67$ [2/3], which is

double the probability that a state can be reconstructed by chance alone [1/3]; Fig 4) – and

13

if the two states were identical (e.g., ancestor=D and descendant=D) then we would assign

that branch to that specific foot posture (e.g., D) partition, but if they differed (e.g.,

ancestor=D and descendant=U), we would assign that branch to a transitional partition.

Branches for which posture states could not be determined – i.e., a single ASR for either

ancestral or descendant nodes cannot be assigned at $P_{ASR} > 0.67$ – were partitioned as

"uncertain" (Fig. S2). Separate rates σ_x^2 of body size evolution were estimated for each

partition (three in total: within-posture [$N = 1,616$]; transitional [$N = 20$]; and uncertain [$N =

18$]) using the local transform option for the VR model in BayesTraits. We accounted for the

large discrepancy in body size between graviportal and non-graviportal taxa within postures

(e.g. elephants in plantigrady, rhinos in digitigrady) by allowing for an offset in means

(intercept) under the VR phylogenetic regression framework (31). Additionally, individual

branches were allowed to vary in rate σ_v^2 (27, 31) on top of the partitioned rates –

minimising the effects of rare and exceptional rate shifts on partition-wise background rate

σ_x^2. We ran the MCMC chain for 10^8 iterations after a burn-in period of 5×10^7 iterations,

sampling every 10^4th iteration. We tested whether σ_x^2 differed amongst the branch

partitions as the proportion of the posterior sample in which the difference in σ_x^2 between

partitions crossed 0 using a critical level of 0.05 ($p_{MCMC} < 0.05$).

Data and BayesTraits infiles containing relevant command lines are provided as

Datasets S1-S22 (see SI for description).

FIGURE LEGENDS

Figure 1. Null hypothesis and prior expectations of evolutionary transitions amongst foot postures.

A, null hypothesis where transitions amongst all foot postures in any direction are equally probable. B, prior expectations of transitions between foot postures based on the phylogenetic distribution of data and the fossil record. Fossil evidences suggest that unguligrady evolved from digitigrady in artiodactyls and perissodactyls. Foot postures are represented by colored silhouettes: black, plantigrady; digitigrady, blue; and pink, unguligrady.

Figure 2. Phylogenetically corrected mean body sizes for each foot posture.

Posterior distributions of estimated body mass accounting for shared ancestry for each foot posture, plantigrady (black), digitigrady (blue), and unguligrady (pink), using a variable-rates (VR) phylogenetic regression model (32) in BayesTraits. Differences between foot postures are calculated as the proportion of the posterior in which differences in estimated coefficients cross zero using a threshold value of 0.05 ($p_{MCMC} < 0.05$). Digitigrady and unguligrady are significantly different from plantigrady ($p_{MCMC} < 0.05$).

Figure 3. Continuous time Markov multistate model.

A, the most frequent transition model in the posterior of models (57% of the posterior). Arrows represent non-zero median transition rates. The reconstructed ancestral mammalian foot posture is plantigrady (denoted by *; probability of state P, $P_P=1$). B, second most frequent transition model (37% of the posterior of models). Arrows represent

non-zero transition rate estimates. Histograms of transition rates across the posterior sample are shown for each non-zero transition. Foot postures are represented by colored silhouettes: black, plantigrady; digitigrady, blue; and pink, unguligrady.

Figure 4. Branch partitions according to nodal states.

Branches were partitioned according to differences in reconstructed nodal posture states or tip states. That is, for each branch of the phylogenetic tree, we compared the states of the ancestral and descendant nodes – using ancestral state reconstructions (ASR) resulting from the top multistate model described in the text (Fig. 3A). We took the single ASR with the highest probability (at $P_{ASR} > 0.67$) – and if the two states were identical (e.g., ancestor=D and descendant=D) then we would assign that branch to the within-posture partition, but if they differed (e.g., ancestor=D and descendant=U), we would assign that branch to a transitional partition. Branches for which posture states could not be determined – i.e., a single ASR for either ancestral or descendant nodes cannot be assigned at $P_{ASR} > 0.67$ – were partitioned as "uncertain". Partitions are colored as shown in the legend inset.

Figure 5. Rates of body size evolution for each branch partition

Separate rates of body size evolution were estimated for each of the branch partitions, based on the state of foot posture along those branches, as in Fig. 4. The transitional partition (purple) is associated with significantly higher rates compared to the within-posture partition (dark grey).
