Abstract

Observational analysis indicates significant decadal changes in daytime, nighttime, and compound (both daytime and nighttime) heat waves (HWs) over China across the mid-1990s, featured by the rapid increase in frequency, intensity, and spatial extent. The spatial variations of these observed decadal changes are assessed by the comparison between the present day (PD) of 1994-2011 and the early period (EP) of 1964-1981. The compound HWs change most remarkably in all three aspects, with frequency averaged over China in the PD tripling that in the EP and both intensity and spatial extent nearly doubling. The daytime and nighttime HWs also change significantly in all three aspects.

A set of numerical experiments is used to investigate the drivers and physical processes responsible for the decadal changes of the HWs. Results indicate the predominant role of the anthropogenic forcing, including changes in greenhouse gas (GHG) concentrations and anthropogenic aerosol (AA) emissions in the decadal changes of the HWs. The GHG changes have dominant impacts on the three types of HWs, while the AA changes make significant influences on daytime HWs. The GHG changes increase the frequency, intensity, and spatial extent of the three types of HWs over China both directly via the strengthened Greenhouse Effect and indirectly via land-atmosphere and circulation feedbacks in which GHG-change-induced warming in sea surface temperature plays an important role. The AA changes decrease the frequency and intensity of daytime HWs over Southeastern China through mainly aerosol-radiation interaction, but increase the frequency and intensity of daytime HWs over

Northeastern China through AA-change-induced surface-atmosphere feedbacks and dynamical changes related to weakened East Asian summer monsoon.

1. Introduction

Heat waves, commonly defined as prolonged period of excessive hot weather, are a distinctive type of high temperature extremes (Perkins and Alexander 2013, Perkins 2015). These high-temperature extremes show increasing occurrence in recent decades as the global mean temperature rises (e.g., Alexander et al. 2006; Donat et al. 2013), leading to severe damages to the human society and ecosystems (e.g. Meehl and Tebaldi 2004; Fischer et al. 2007; Coumou and Rahmstorf 2012; Seneviratne et al. 2014; Sun et al. 2014). For instance, the extreme long-lasting heat wave over Europe during the summer of 2003 caused about 66 000 deaths (e.g. Schär and Jendritzky 2004; Robine et al. 2008) and the record-breaking heat wave over western Russia during July of 2010 yielded a death toll of 11 000 and grain-harvest losses of 30% (e.g. Coumou and Rahmstorf 2012; Matsueda 2011). The disastrous impact of heat waves on the human lives, agriculture, and economies highlights the urgency of understanding the changes of heat waves and associated physical processes.

Since the mid-1990s, heat waves have become more frequent and severe across China (You et al. 2017; Li et al. 2017; Luo and Lau 2017; Wang et al. 2017, Freychet et al. 2018a). Several devastating heat waves in recent decades, such as the 2013 July-August heat wave in Central and Eastern China and the 2015 summer heat wave in Western China have caused considerable damages to agricultural production and human

health (e.g. Sun et al. 2016; Ma et al. 2017). The 2013 July-August heat wave in Central and Eastern China lasted more than 30 days (Zhou et al. 2014; Ma et al. 2017) and the regionally averaged surface air temperature broke the historical record, exceeding the observed 1961–1990 climatology by 1.89 °C. The 2015 summer registered the hottest summer over western China, with the area-averaged summer daily mean, maximum, and minimum surface air temperatures breaking the historical records (Sun et al. 2016). In addition, Northeast China experienced a hot summer in 2014, which is associated with decrease in precipitation (Wilcox et al. 2015a).

Previous studies demonstrated a crucial role of anthropogenic activity in increasing the occurrence of the extreme temperatures and long-lasting heat waves over China (Wen et al. 2013; Sun et al. 2014; Lu et al. 2016; Freychet et al. 2017; 2018a, b; Chen and Dong 2018), as well as intensifying the magnitude of the extreme temperatures (Yin et al. 2017). Most of those studies focused on all combined anthropogenic impact, rather than the individual effect of anthropogenic forcing. For instance, the individual role of changes in greenhouse gases concentrations (GHG) and anthropogenic aerosol (AA) emissions in the changes of long-lasting heat waves are not clear.

Different anthropogenic forcings influence the atmospheric temperature through distinct thermodynamic and dynamical processes, but the mechanisms related to the responses of HWs to different anthropogenic forcings have not been fully understood yet. The increase in GHG concentrations warms the atmosphere by absorbing more outgoing longwave radiation (e.g., Cubasch et al. 2001; Dong et al. 2009). At the same time, the atmospheric temperature are also affected by the circulation changes due to

the GHG concentration changes. The increased GHG concentrations enhance the southern part of East Asia Summer Monsoon (EASM) circulation, which results from the competing effects of the increase in moisture static energy related to the strengthened land-sea thermal contrast and the mid-troposphere convective barrier associated with the reduced relative humidity in a warming world (Lau and Kim 2017; Lau et al. 2017). In addition, the strengthened land-sea thermal contrast is determined by the direct GHG radiative effect (Li and Ting 2017,Tian et al. 2018). The changes of AA emissions affect the surface and atmospheric temperature by directly scattering and absorbing the solar radiation through aerosol-radiation interaction and by changing the cloud properties through aerosol-cloud interaction (e.g. Rosenfeld et al. 2008; Stevens and Feingold 2009; Tao et al. 2012; Li et al. 2016b). Not only the local AA emission changes, but also the remote AA emission changes have an impact on the summer extreme temperatures over China through aerosol change induced precipitation-soil moisture-cloud-temperature feedbacks (Dong et al. 2016a; 2016b). Local summer warming associated with reduced precipitation leads to decrease in evaporation and less cloud cover since precipitation deficit induces drying soil. Increased solar radiation at the surface associated with less cloud cover and decreased upward latent heat fluxes associated with reduced evaporation cause a positive feedback to the surface warming. Moreover, the dynamical feedbacks of reduced the EASM circulation and rainfall, which induced by the weakened land-sea thermal contrast and more stable atmosphere in response to the increase in AA emissions, could also have an impact on atmospheric temperature (Guo et al. 2013, Li et al. 2016b; Li et al. 2018b, Tian et al. 2018).

Up to now, the heat waves are precisely classified into three categories (e.g., Chen and Li 2017; Chen and Zhai 2017): daytime (only hot in day), nighttime (only hot at night), and compound ones (hot in both day and night), since extreme high temperature at night, inducing great heat-related morbidity and mortality (Hajat et al. 2006; Gosling et al. 2009), is noticed as disastrous as that in daytime. These three types of heat waves are of different features and associated with different mechanisms (e.g. Chen and Li 2017; Chen and Zhai 2017; Hong et al. 2018). However, most of the previous studies focused on the characteristics and changes of daytime heat waves (e.g., Ding et al. 2010; Guo et al. 2017; Luo and Lau 2017; Lu and Chen 2016; Wang et al. 2017). The changes of compound and nighttime heat waves, especially drivers and physical mechanisms for the recent decadal change, are not well understood (You et al. 2017; Li et al. 2017, Luo and Lau 2017). Also, the individual contributions of changes in GHG concentrations and AA emissions to the recent decadal changes in heat waves are not evaluated and the associated physical processes are not revealed yet, since the previous studies assessed all anthropogenic impacts together (e.g., Sun et al. 2016; Ma et al. 2017). Therefore, the main aims of this work are to revisit the time evolutions in the three types of heat waves over China in observations with a focus on the recent decadal changes across the mid-1990s, to quantify the relative roles of changes in GHG concentrations and AA emissions in shaping these decadal changes, and to understand the associated physical processes.

The structure of this paper is organized as follows: The observed decadal changes in heat waves over China are revisited in Section 2. The model and experiments are

described briefly in Section 3. The simulated changes in response to different changes in anthropogenic forcings are shown in Section 4. The physical processes responsible for simulated changes in heat waves forced by different anthropogenic forcings, such as GHG concentrations and AA emissions, are illustrated in Section 5. Conclusions are summarized in Section 6.

2. Observed decadal changes in heat waves over China

2.1 Observational datasets

Observations used in this are the homogenized datasets of daily maximum temperature (Tmax) and minimum temperature (Tmin) in 753 stations over China during 1960-2013 (Li et al. 2016a). Regarding to distinct local climate in China, the HWs over three sub-regions are also analyzed, which are Southeastern China (SEC, south of 35ºN and east of 105ºE), Northeastern China (NEC, north of 35ºN and east of 105ºE), and Western China (WC, west of 105ºE). There are 334, 224, and 195 stations in SEC, NEC, and WC, respectively. Fig. 2g shows the distributions of the stations over these three sub-regions. This study focuses on the extended summer (May–September) HWs.

2.2 Definition of HWs

A HW is defined as a weather event with daily temperature exceeding a threshold continuously for a few days (e.g., Perkins and Alexander 2013). Both absolute and relative thresholds could be used to define a heat wave. The absolute threshold is a fixed temperature value, such as 35℃ (e.g., Tan et al. 2007; Sun et al. 2014), while the

158 relative threshold is decided by local climate, varying at different places on different
159 dates (Stefanon et al. 2012). Concerning the various climate types in China, the relative
160 threshold is employed to define the heat waves in this study and it has also been widely
161 used in some previous studies (e.g., Li et al. 2017; Wang et al. 2017). The relative
162 threshold on each calendar day is calculated as the daily 90^{th} percentile of Tmax or
163 Tmin based on 15-day samples centered on that day during the baseline period of 1964-
164 1981 (i.e. total samples 15*18 = 270 days, Della-Marta et al. 2007). A HW is defined
165 when the daily temperature is higher than the relative threshold for at least three days.
166 All the HWs are categorized to three independent types:

167 (1) compound HW - at least **three** consecutive days with simultaneous hot days and
168 hot nights (Tmax $\geq 90^{th}$ percentile and Tmin $\geq 90^{th}$ percentile).

169 (2) daytime HW - at least **three** consecutive hot days (only Tmax $\geq 90^{th}$ percentile),
170 without consecutive hot nights.

171 (3) nighttime HW - at least **three** consecutive hot nights (only Tmin $\geq 90^{th}$ percentile),
172 without consecutive hot days.

173 Three indicators, i.e. frequency, intensity, and spatial extent, are used to measure the
174 HWs in a year. The frequency is represented by the accumulated occurrence of events
175 within a year. The intensity of each event is calculated by averaging the everyday
176 temperature anomalies within an event, which are obtained by subtracting the
177 corresponding threshold from the daily temperatures. Particularly, the intensity of
178 compound HWs is the sum of the averaged Tmax and Tmin anomalies. The intensity

for a year is computed by averaging the intensity of events occurring in that year. The spatial extent is calculated through a "frozen grid" scheme (Jones et al., 1986). The mainland of China is divided into 1.875° longitude × 1.25° latitude boxes, with a total number of N. There are $n(i)$ stations in total situated in box i, in which $nh(i, t)$ stations experience at least one extreme event during the extended summer in year t. Then the spatial extent in year t is computed as $\sum_{i=0}^{i=N} \frac{nh(i,t)}{n(i)} \times 1.875 \times 110 \times 1.25 \times 110$, in which "110" denotes an approximate distance per unit longitude/latitude.

2.3 Observed decadal change

Figure 1 shows the time evolution of the area averaged frequency and intensity as well as the spatial extent of the compound, daytime, and nighttime HWs. The timeseries of the three properties of compound and nighttime HWs seems to be dominated by linear trends on low frequency time scale, while those of daytime HWs are featured by abrupt decadal changes. These could be attributed to that the changes in compound and nighttime HWs are predominantly contributed to by the changes of GHG concentrations, which show an increasing trend (Le Quere et al. 2009), and the changes in daytime HWs are partly influenced by the AA changes, which show significant decadal changes across mid-1990s (Lamarque et al. 2010), which are indicated by the results in section 4. What is interesting, the frequency and intensity of one type of HWs are highly correlated with the correlation coefficient for whole China of 0.90, indicating highly coupled interannual variations of frequency and intensity of one type of HWs. However, the interannual variations is not the concern of this study, which would not be explored more in this paper.

All three type HWs over China experienced an abrupt decadal change across the mid-1990s, characterized by increases in frequency, intensity, and saptial extent (Figure 1). These rapid decadal changes are robust features and they are not sensitive to the baseline period used to find the relative thresholds and define HWs. In the rest of this paper, HWs are defined using the relative thresholds based on the period of 1964-1981. Comparing to daytime and nighttime HWs, compound HWs exhibited the most dramatic changes in all three aspects. The frequency of compound HWs during 1994-2011 (present day, PD hereafter) almost tripled that during 1964-1981 (early period, EP hereafter), rising from 0.67 events per year to 1.85 events per year (Table 2). These two periods were chosen to avoid years with a strong impact of the volcanic eruptions (Dong et al. 2017). The intensity of compound HWs doubled the value of the EP after mid-1990s, with the value changing from 1.42 °C to 3.09 °C (Table 2). The spatial extent of compound HWs expanded from 3.66×10^6 km^2 to 6.97×10^6 km^2 (Table 2). The decadal changes of daytime HWs show some similar features in comparison with the compound ones, but with relatively small magnitude. The frequency and intensity of daytime HWs increased by 0.7 events per year and 0.29 °C (Table 2). The spatial extent expanded from 8.38×10^6 km^2 to 8.86×10^6 km^2 (Table 2), in comparing with the whole China area of 9.63×10^6 km^2. The nighttime HWs also showed decadal increases in all three aspects. The frequency of nighttime HWs exhibited a sharp increase across mid-1990s, changing from 1.76 events per year to 3.72 events per year, which means that there are averaged two more nighttime HWs over China in every summer during the PD relative to the EP (Table 2). The intensity of nighttime HWs enhanced significantly by 0.41 °C

(Table 2). The influencing area increased by about 20% (Table 2). In addition, the frequency and intensity of the three types of HWs averaged over the three sub-regions show similar rapid decacal changes as those averaged over whole China. Moreover, all the area averaged changes above are calculated based on station data. The area averaged changes are also computed after interpolating station data to regular grids and they are nearly identical to the ones based on station data.

Figure 2 illustrates the spatial patterns of the decadal changes in frequency and intensity of the three types of HWs over China across the mid-1990s in observations. Nearly all the decadal changes in each indicator of three type HWs are positive throughout China, but with different spatial patterns. The occurrence of compound HWs increased the most over the northern part of China, mid-lower Reaches of the Yangtze River, and the Delta of the Pearl River, with an increase in frequency more than 2.0 events per year (Fig. 2a). The changes of intensity of compound HWs share a similar spatial distribution with the frequency (Fig. 2b), with the maximum of intensity changes located at the northern part of China (about 4.8 °C). The spatial patterns of changes in frequency and intensity for daytime and nighttime HWs show some distinct features with increases in both frequency and intensity for nighttime HWs being stronger than those for daytime HWs (Fig. 2c-f). The significant increase of frequency of daytime HWs primarily appeared in the northern part of China, especially in the western part of China with the value of about 2.5 events per year (Fig. 2c), while the significant intensification in magnitude of daytime HWs around 0.6 °C mainly occurred in the central part of China (Fig. 2d). The frequency of nighttime HWs increased

significantly in the northern part of China (Fig. 2e), with a range of 1.5 to 3.0 events per year. The largest increase is situated on the south frank of the Tibetan Plateau with the maximum of 6.2 events per year. The intensity of the nighttime HWs significantly enhanced in the northern part of China (Fig. 2f), with the maximum of 1.1 °C. Interestingly, the nighttime HWs in the central-eastern China exhibited large increase in frequency and intensity, while the daytime HWs over there showed the opposite changes, with frequency decreasing and intensity weakening slightly and the compound HWs over there displayed little changes. Previous studies investigating the linear trends of the HWs also reported similar changes in these three types of HWs in the central-eastern China (Ding et al. 2010; Chen and Li 2017; Freychet et al. 2017). However, the physical mechanism for the trends in these three type HWs is still not clear.

3. Model and experiments design

The above results show that the observed three types of HWs exhibited significant decadal changes across the mid-1990s. A set of numerical experiments is performed to assess whether the anthropogenic forcings (GHG concentrations and AA emissions) contribute to these decadal changes in observations, and what the relative roles of individual forcing are, and what the main physical processes involved are.

3.1 Model and experiments design

This study used an atmosphere-ocean-mixed-layer coupled model, MetUM-GOML1 (Hirons et al. 2015) by performing a set of numerical experiments, to estimate the contributions of combined GHG and AA changes or individual forcing change on the

decadal changes of three type HWs in China. MetUM-GOML1 is a coupled model comprising of the atmosphere component of the Met Office Unified Model at the fixed scientific configuration Global Atmosphere 3.0 (GA3.0; Arribas et al. 2011; Walters et al. 2011) and a Multi-Column K Profile Parameterization (MC-KPP) mixed-layer ocean model. The vertical MC-KPP columns are configured over 100 levels within a depth of 1000 m using a stretch function, so the vertical resolution of MC-KPP is 1.2m at the surface and about 2 m over the first 41.5 m near the surface. Since MC-KPP includes only vertical mixing processes and does not include ocean dynamics, the corrections of temperature and salinity are applied. In the corrections, the mean ocean advections are represented by the prescribed seasonally-varying 3-dimension temperature and salinity fluxes, which also account for the biases in atmospheric surface heat and fresh water fluxes. The frequency of coupling between atmospheric and oceanic components is once every three hours. The advantages of this atmosphere-ocean-mixed-layer coupled model are less computational time and smaller biases in simulated sea surface temperature than the fully coupled ones (Hirons et al. 2015, Dong et al. 2017; Luo et al. 2018). All experiments are run at the horizontal resolution of 1.875° longitude by 1.25° latitude with 85 vertical levels in the atmosphere.

Table 1 summarized the performed experiments in this study. First of all, a relaxation experiment (R0) for 12 years was performed. In relaxation experiment, the PD GHG and AA forcings (Lamarque et al. 2010; 2011) are used and the ocean temperature and salinity were relaxed to a PD (1994-2011) climatology, which is derived from the Met Office ocean analysis (Smith and Murphy, 2007). The climatological seasonal cycle of

daily mean 3D ocean temperature and salinity corrections are obtained from the relaxation experiment. These ocean temperature and salinity corrections are then applied to the free-running coupled experiments. Four other time-sliced experiments are performed by using different forcings, i.e. C-EP experiment forced by the EP (1964–1981) mean GHG concentrations and appropriate AA emissions, C-PD experiment forced by the PD (1994–2011) mean GHG concentrations and AA emissions, C-PD-GHG experiment forced by the PD mean GHG concentrations, but the appropriate EP mean AA emissions, C-PD-AA experiment forced by the PD mean AA emissions, but the EP mean GHG concentrations. All experiments are run for 50 years and use the climatological PD sea ice extent from HadISST (Rayner et al. 2003). The same set of experiments was used to investigate the forced decadal summer precipitation change over East Asia in Tian et al. (2018) and the decadal changes of temperature extremes over China in Chen and Dong (2018). The last 45 years of each experiment are used for analysis. The HWs in the experiments are defined by the same way as in observations, expect that the relative threshold on each day is calculated as the daily 90^{th} percentile of Tmax or Tmin based on 15-day samples centered on this day during the last 45 years of C-EP experiment (i.e. total samples 15*45 = 675 days). The difference between a pair of experiments that include and exclude a particular forcing indicates the response to that forcing. The difference between C-PD and C-EP indicates the combined effect of changes in both GHG concentrations and AA emissions (hereafter ALL forcing). The impact of changes in GHG concentrations (hereafter GHG forcing) is the difference between C-PD-GHG and C-EP and the impact of changes in

AA emissions (hereafter AA forcing) is the difference between C-PD-AA and C-EP. Statistical significance of the mean changes are assessed using a two tailed Student *t*-test.

3.2 Model climate for Tmax and Tmin

The climatological means of Tmax and Tmin in the C-PD experiment for the extended summer are compared with the observed ones during PD (Fig. 3). The observed Tmax means show more or less uniform distributions over the southeastern part of China with value higher than 29 °C, decreasing northward with value about 23-26^{o}C over the northeastern part of China. Over western China, a low value centre is located over the Tibetan Plateau and a high value centre over northwestern part of China with temperature above 29 °C (Fig. 3a). The climatological means of observed Tmin exhibit great meridional gradient over eastern part of China with the maximum higher than 23 ^{o}C in southeast coast of China and minimum of 8-11^{o}C over Northeast China. The spatial distribution of Tmin over western China shows a minimum (less than 2^{o}C) over the Tibetan Plateau and a high value (14-20^{o}C) over northwestern part of China, being similar to spatial pattern in Tmax (Fig. 3b). The spatial patterns of climatological extended summer means of Tmax and Tmin in the C-PD experiment and regional magnitudes agree well with the observed ones with pattern correlation coefficients of 0.82 for Tmax and 0.88 for Tmin (Fig. 3c and d). The observed Tmax distributions are reproduced by the model over southeastern and northwestern part of China with value above 29 °C, but slightly underestimated over the Tibetan Plateau and northeastern part of China (Fig. 3d). The observed Tmin distributions are also well simulated by the

model, with some underestimation over the Tibetan Plateau (Fig. 3c). These results indicate that the model reproduce many features of the extended summer climatological means of Tmax and Tmin in observations, suggesting that the model used in this study is appropriate for investigating the response of the temperature extremes related HWs to different anthropogenic forcings.

4. Model simulated responses to different anthropogenic forcings

4.1 Spatial pattern of responses to different forcings

Figure 4 shows the spatial patterns of changes in frequency and intensity of the compound HWs in response to different anthropogenic forcings in model experiments. The significant increases in the frequency and intensity throughout China and their spatial distributions in observations (Fig. 2a and b) are well reproduced by the ALL forcing experiment (Fig. 4a and b). The spatial patterns of the increases in the model experiment are consistent with the observed ones with relatively large increase in frequency and strong enhancement in intensity over the northern part of China and mid-lower Reaches of Yangtze River, though the magnitudes of the changes in response to ALL forcing for increases in frequency are smaller than the observed ones. These results demonstrate that the observed decadal increases in occurrence and intensity of compound HWs over China across the mid-1990s are predominantly attributed to the anthropogenic GHG and AA changes.

Furthermore, the changes of compound HWs in response to GHG forcing share very similar patterns with the changes in the ALL forcing experiment (Fig. 4c and d), while

353 the changes driven by the AA forcing are relatively weak, except of some local
354 significant decreases in frequency and intensity over SEC (Fig. 4e and f). Thus,
355 comparing the responses to only GHG with those to only AA changes indicates that the
356 GHG changes play a dominant role in the increase in frequency and intensity of
357 compound HWs. In addition, the model overestimates the increase in frequency of
358 compound HWs over the southwestern part of China, which is resulted from the GHG
359 impact (Fig. 2a and Fig. 4a and c).

360 The changes of daytime HWs in response to the different forcings are shown in figure
361 5. The principle features of the changes of daytime HWs in the ALL forcing experiment
362 are significant increases in frequency and intensity over the northern part of China (Fig.
363 5a and b). These main features show some similarities with the observed changes (Fig.
364 2c and d). However, the changes in the intensity of daytime HWs over the northern part
365 of China are overestimated, but those over the central part of China are underestimated.
366 Both the GHG and AA forcing changes are important to the changes of daytime HWs.
367 Responses to the GHG forcing share the similar spatial patterns with those in the ALL
368 forcing experiment, with a little difference in the magnitude of changes, indicating the
369 dominant role of GHG changes in affecting the daytime HWs (Fig. 5c and d). Changes
370 of the daytime HWs induced by the AA impact exhibit dipole patterns over China with
371 increases over northern China and decreases or weak changes over southern China (Fig.
372 5e and f). In addition, the responses to AA forcing are of more significance for daytime
373 HWs than for compound HWs, implying greater AA impact on the daytime HWs.

374 Responses of the nighttime HWs to the different forcings are shown in figure 6. In

375 comparison with observed changes shown in Fig. 2, the model reproduces significant
376 increases in the frequency and intensity of the nighttime HWs over the northern part of
377 China in response to ALL forcing changes (Fig. 6a and b). Comparison between
378 responses to different forcings illustrates that the significant changes of the nighttime
379 HWs in the model simulations are primarily due to the GHG changes (Fig. 6c and d)
380 with impacts of changes in AA being generally weak (Fig. 6e and f). Additionally, the
381 increases in frequency over the southeastern part of China are overestimated, because
382 the GHG changes induce strong increases over there but the AA changes result in weak
383 decreases.

384 **4.2 Area averaged responses to different forcings**

385 The area averaged changes in frequency and intensity and changes in spatial extent
386 of the three types of HWs over whole China and all three sub-regions for both
387 observations and model experiments are demonstrated in Figure 7. Quantitatively, the
388 changes of the three types of HWs in response to ALL forcing changes simulated by
389 models are in some agreement with observations, not only over China as a whole, but
390 also over the individual sub-regions, though the magnitudes of the changes in the model
391 are slightly different from the observed ones.

392 For the compound HWs, in response to ALL forcing, the area averaged changes in
393 frequency and intensity over the whole mainland China are 0.75 events per year and
394 1.07 °C, which are about 2/3 of the observed 1.18 events per year and 1.67 °C (Fig. 7a
395 and b), and the change in spatial extent over whole China is 3.54×10^6 km^2, very close

396 to the 3.31×10^6 km^2 in observations (Fig. 7c). Moreover, the simulated increases in
397 frequency (intensity) averaged over the SEC and WC are very similar to the observed
398 changes, but increases in frequency (intensity) over the NEC are weaker than
399 observed changes. The simulated changes in spatial extent over the three sub-regions
400 are also consistent with observations. Furthermore, the changes of GHG explain most
401 responses in the simulated changes of compound HWs over whole China or over the
402 three sub-regions, indicating the predominant role of GHG changes in affecting the
403 compound HWs.

404 For the daytime HWs, the changes in frequency and intensity averaged over whole
405 China and the three sub-regions in the ALL forcing experiment are close to those in the
406 observations, with simulated changes over whole China of 0.93 events per year and
407 0.38 °C relative to the observed ones of 0.70 events per year and 0.29 °C (Fig. 7d and
408 e). The simulated change in spatial extent is overestimated (Fig. 7f). Similar with the
409 compound HWs, the area averaged changes of the daytime HWs are primarily induced
410 by the GHG changes. However different from the compound HWs, the changes of
411 daytime HWs over the NEC and SEC are significantly influenced by the AA changes.
412 The changes in frequency and intensity of daytime HWs over the NEC in response to
413 AA forcing are 0.35 events per year and 0.15 °C, while they are -0.28 events per year
414 and -0.12 °C over the SEC. These significant increases over the NEC and decreases
415 over the SEC are consistent with the dipole pattern of AA induced changes in frequency
416 and intensity (Fig. 5e and f).

417 For nighttime HWs, the simulated changes in most aspects agree well with the

observed ones except the change in frequency over NEC and the GHG changes play a key role in leading to the changes in frequency, intensity and spatial extent. The changes in frequency and intensity of nighttime HWs averaged over whole China in response to ALL forcing are 1.66 events per year and 0.36 °C, close to 1.96 events per year and 0.41 °C in observations (Fig 7g and h). The simulated change in spatial extent is greater than the observed changes in whole region, SEC, and WC (Fig. 7i).

There is some nonlinearity for the changes in frequency and intensity for all three type HWs, especially strong for daytime HWs over the SEC in response to GHG and AA changes in model simulations, evidenced by the sum of the responses to separate GHG and AA forcing being not equal to the response to the ALL forcing. The nonlinearity is weak for changes of daytime HWs averaged over whole China and over other two sub-regions and all the area averaged changes of compound and nighttime HWs. The nonlinearity of responses to different forcings has noticed by previous studies (Feichter et al. 2004, Ming and Ramaswamy 2009, Shiogama et al. 2012). However, detailed discussion of this nonlinearity is beyond the scope of this study.

The results above indicate that the observed decadal changes in the frequency, intensity and spatial extent of compound, daytime, and nighttime HWs over China across the mid-1990s are primarily forced by the changes in anthropogenic forcings, such as GHG concentrations and AA emissions. The impact of GHG changes and that of AA changes are different in many aspects. GHG changes contribute dominantly to the increases in all aspects of the three types of HWs over most regions in China, while AA changes significantly increase the frequency and intensity of the daytime HWs over

NEC, but decrease them over SEC.

5. Physical processes responsible for the simulated decadal changes of HWs

The physical processes responsible for the decadal changes of the three types of HWs in response to different forcings are discussed in this section by diagnosing the seasonal mean responses. The changes of HWs could be contributed by the changes in the climatological seasonal mean temperature and the changes in temperature variability. The contribution of changes in variability is estimated by calculating the properties of three types of HWs in the C-PD simulation by removing the climatological extended-summer Tmax and Tmin differences between the C-PD and C-EP simulations relative to C-EP simulation and by comparing these new estimated changes with changes diagnosed from original C-PD simulation relative to C-EP simulation. Results indicate that removing the climatological mean state change nearly eliminate changes (not shown) in all properties of three type HWs over China seen in response to ALL forcing. These indicate little contribution of changes in temperature variability and suggest that the decadal changes of the three types of HWs in response to ALL forcing are predominantly attributed to the changes in the climatological seasonal mean temperature between C-PD and C-EP simulations. This conclusion is in agreement with Argueso et al. (2016) who showed that seasonal mean temperature changes control future heatwaves in most regions globally. Therefore, it is reasonable to examine the changes in the climatological seasonal mean state to discuss the associated physical processes.

461 **5.1 Induced by GHG forcing**

462 The spatial patterns of extended-summer-mean changes of some key variables in
463 response to GHG changes are illustrated in Figure 8. The increased downward clear sky
464 surface LW radiation (6.01 W m^{-2} over NEC, 6.64 W m^{-2} over SEC, and 5.35 W m^{-2}
465 over WC, Fig. 8a) indicates the warmer atmosphere induced by the increase in GHG
466 concentrations via the Greenhouse Effect and related feedbacks. The downward surface
467 clear sky LW radiation increases more over SEC due to more increase of water vapor
468 in the atmosphere (2.08 kg m^{-2} over SEC; Fig. 8b). The enhanced moisture transport
469 from the South China Sea to SEC and moisture transport convergence (not shown) are
470 responsible for moistening atmosphere over SEC. The enhanced moisture transport is
471 induced by more water vapor evaporated from the warmer ocean and the southwesterly
472 anomalies around the coast in SEC (Fig. 8d), which are related to the strengthened land-
473 sea thermal contrast resulting from larger warming over land than over ocean (Fig. 8c).
474 The enhanced moisture transport convergence over SEC is attributed to the increased
475 moisture static energy related to more water vapor transport and the enhanced Western
476 North Pacific Subtropical High (Fig. 8d) induced by the strengthened local Hadley
477 circulation resulting from the increased tropical sea surface temperatures in response to
478 GHG changes (Tian et al. 2018). These circulation and sea surface temperature
479 responses are consistent with the previous studies (Lau and Kim 2017; Lau et al. 2017).
480 The increase of net surface SW radiation is significant over NEC and WC (0.91 W m^{-2}
481 over NEC and 2.06 W m^{-2} over WC; Fig. 8e), which warms the land surface in situ.
482 The positive anomalies of shortwave cloud radiative effect (SW CRE; 1.77 W m^{-2} over

NEC and 1.75 W m^{-2} over WC; Fig. 8f) associated with the reduction of cloud cover over NEC and WC (Fig. 8g) result in the increased surface SW radiation. The reduction of cloud cover over NEC and WC is associated with large decrease in relative humidity (Fig. 8h) since the water vapor in the atmosphere over land is mainly controlled by transport from ocean and constrained by ocean warming and increases less than saturation specific humidity following the Clausius-Clapeyron relationship because stronger warming over land than over ocean (e.g., Dong et al. 2009; Boé and Terray 2014). In summary, the seasonal mean land surface and therefore surface air temperature (Tmax and Tmin) during extended summer increases directly by the strengthened Greenhouse Effect over whole China and indirectly by the positive LW feedback related to the increase in water vapor over SEC associated with circulation changes in response to GHG changes and by the positive SW feedback corresponding to the decrease in cloud cover over WC and NEC in which GHG change induced warming in sea surface temperature plays an important role for the water vapor and circulation changes. As a result, all the frequency, intensity, and spatial extent of these three types of HWs are increased. Particularly, the positive LW feedback over SEC plays an important role in the increase in frequency of compound and nighttime HWs, while the positive SW feedback over WC and NEC dominates the increase in frequency of daytime HWs and the increase in intensity of all three types of HWs.

5.2 Induced by AA forcing

The spatial patterns of summer mean changes of some key variables in response to AA changes are illustrated in Figure 9. The total aerosol optical depth (AOD) increases

505 over most part of China (Fig. 9a), resulting in the reduction of the surface clear sky SW
506 radiation (-2.97 W m^{-2} over China; Fig. 9b) through aerosol-radiation interaction, then
507 leading to surface cooling. Especially, the surface air temperature over SEC (-0.28 °C;
508 Fig. 9h) decreases greatly due to much larger decrease in surface SW radiation (-6.37
509 W m^{-2} over SEC; Fig. 9c). However, although the AOD increases over NEC around
510 40°N, the surface SW radiation does not decrease much, because significant positive
511 changes of SW CRE over NEC (1.42 W m^{-2} over NEC; Fig. 9d) contributed to by the
512 decrease in cloud cover (Fig. 9e) offset the decrease in surface clear sky SW (Fig. 9b)
513 and warm the surface air (Fig. 9h). The decrease in cloud cover is associated with the
514 decrease in rainfall over NEC (Fig. 9f), which is featured by weakened EASM induced
515 by decreased land-sea thermal contrast and weakened atmospheric stability (Tian et al.
516 2018). In addition, Zhang et al. (2017) addressed that the increase in AA emission
517 induces the increase in the frequency of summer drought over North China by using the
518 Coupled Model Intercomparison Project Phase 5 (CMIP5) model simulations.
519 Furthermore, the reduced precipitation over NEC leads to decrease in soil moisture (Fig.
520 9g) and decrease in evaporation (not shown), reducing the upward latent heat fluxes
521 (not shown). This increased SW radiation due to decreased cloud cover and reduced the
522 upward latent heat fluxes due to decreased soil moisture and evaporation exert a
523 positive feedback to warm the surface and therefore surface air (Fig. 9h). Therefore, it
524 is the decrease in surface clear sky SW radiation related to the increase of AOD (Fig.
525 9a and b) that induces the decreases in frequency and intensity of daytime HWs over
526 SEC through aerosol-radiation interaction. On the other hand, it is the increased SW

CRE over NEC (Fig. 9d) related to weakened EASM overwhelming the decrease in clear sky SW radiation (Fig. 9b) and the local precipitation-soil moisture-temperature interactions that jointly cause the increases in the frequency and intensity of daytime HWs over NEC.

6. Conclusions

The decadal changes across the mid-1990s of three types of HWs, i.e. compound HWs, daytime HWs, and nighttime HWs, during extended summer (May–September) are detected on the aspects of frequency, intensity, and spatial extent by using the Chinese station dataset. A set of numerical time-sliced experiments is performed by an atmosphere-ocean-mixed-layer coupled model to assess the role of anthropogenic forcings, including changes in GHG concentrations and AA emissions, in generating the decadal changes of the three types of HWs, and to evaluate the different contributions of individual GHG forcing and individual AA forcing to the HW decadal changes and to understand physical processes involved. The principle results are concluded as follow.

The three types of HWs over China experienced significant rapid decadal changes across the mid-1990s, featured by the increase in frequency, the enhancement in intensity, and the expansion in spatial extent. The compound HWs change most remarkably in all three aspects. The changes of daytime and nighttime HWs are also significant, though not as dramatic as changes of the compound HWs.

Results of the model simulations demonstrate that the anthropogenic forcing,

548 including changes in GHG concentrations and AA emissions, has played a predominant
549 role in generating the observed decadal changes in the frequency, intensity and spatial
550 extent of the three types of HWs. The spatial patterns of changes of the three types of
551 HWs are well reproduced by the atmosphere-ocean-mixed-layer coupled model
552 MetUM-GOML1 in response to changes in GHG and AA forcings together (ALL
553 forcing). Quantitatively, simulated changes in frequency and intensity over China and
554 over three sub-regions in response to ALL forcing are also comparable to the observed
555 changes.

556 Individually, GHG changes dominantly result in the simulated changes of the three
557 types of HWs in response to ALL forcing, while AA changes make a relatively weak
558 contribution, and the changes in GHG and AA forcing have distinct impacts on the
559 changes of the three types of HWs. Changes in GHG concentrations play a crucial role
560 in increasing the frequency, intensity, and spatial extent of all three types of HWs over
561 China. Changes in AA emissions have a weak influence on compound and nighttime
562 HWs. However, AA changes significantly increase the frequency and intensity of
563 daytime HWs over NEC and decrease them over SEC.

564 The GHG changes increase the frequency, intensity, and spatial extent of the three
565 types of HWs both directly via the strengthened Greenhouse Effect and indirectly via
566 atmosphere and circulation feedbacks in which GHG change induced warming in sea
567 surface temperature plays an important role. Over the sub-regions of WC and NEC,
568 warmer atmosphere due to the increase in GHG concentrations, accompanied with
569 limited increase in water vapor in the atmosphere, results in the reduction of cloud cover.

570 Increased surface downward SW radiation, resulted from positive SW cloud radiative
571 effect over WC and NEC, heats the surface and warms the surface air as a positive
572 feedback. Over the sub-region of SEC, the increase of water vapor in the atmosphere,
573 induced by the enhanced moisture transport and moisture transport convergence over
574 SEC due to the circulation changes and warming in sea surface temperature in response
575 to GHG changes, has a positive feedback on surface warming.

576 The AA changes significantly decrease the frequency and intensity of daytime HWs
577 over SEC through aerosol-radiation interaction and increase them over NEC by the AA
578 change induced rainfall change and atmosphere-surface feedbacks related to weakened
579 East Asian summer monsoon. Increased AOD over eastern part of China directly
580 reduces the surface SW radiation and decreases the surface temperature and surface air
581 temperature over SEC and therefore the frequency and intensity of daytime HWs.
582 Reduced cloud cover over NEC, resulting from the decrease in convection in response
583 to AA changes, increases the surface SW radiation and warms the surface and surface
584 air. The reduced rainfall also leads to decreased upward latent heat fluxes due to
585 decreased soil moisture, which cooperated with the increased SW radiation related to
586 less cloud cover tends to warm the surface. These surface feedbacks overwhelm the
587 direct cooling impact induced by increase in AA emissions and lead to increases in the
588 frequency and intensity of daytime HWs over NEC.

589 The results demonstrate the dominant contributions of anthropogenic changes,
590 especially the increased GHG concentrations, to the observed decadal changes in
591 frequency, intensity, and spatial extent of the three types of HWs over China during

592 extended summer across the mid-1990s. The GHG changes raise the mean surface air
593 temperature and air column temperature, increasing all the aspects of the three types of
594 HWs nearly over whole China with important water vapor feedbacks associated with
595 GHG induced sea surface temperature changes. The AA changes have different local
596 impacts. Local interaction between reduced precipitation, cloud cover, soil moisture,
597 evaporation, and temperature related to weakened East Asian summer monsoon play
598 an important role in warming the surface atmosphere over NEC and therefore changing
599 the properties of daytime HWs.

600 Looking for a few decades ahead, GHGs will continue to increase while aerosol
601 emissions over China are expecting to decrease. China would experience more HWs
602 for different types over different regions with greater severity and the areas affected by
603 severe HWs would also be expanded. Therefore, better strategies for adaptation and
604 mitigation against different types of HWs over different regions would benefit the
605 people and society.

606 This paper primarily investigates the individual roles of GHG concentrations and AA
607 emissions in the decadal change of the three types of HWs over China. There are some
608 other factors that could affect the decadal change of HWs over China, such as the land
609 use and land cover change (Findell et al. 2017, Li et al. 2018a) and the phase shift of
610 Atlantic Multi-decadal Oscillation, which might have contributed to warming over the
611 Eurasian continent around mid-1990s (Hong et al. 2017). More effort is needed to
612 quantify their contributions to the recent decadal changes of HWs over China.

Moreover, the responses to AA forcing are influenced not only by the AA emissions, but also by climatology, aerosol transport and deposition, and chemical processes in the model. All these processes affect the distribution of aerosol burden (e.g., Wilcox et al. 2015b) and suggest a possible model dependence of the responses to AA forcing. Wang et al. (2018) pointed out that there are large intermodel spread of responses to AA forcings in different climate models. These model dependence and intermodel uncertainty of the responses call for improved model to investigate the responses to AA forcings.

Tables

Table 1. Summary of numerical experiments: Note that a slightly different period of

1970-1981 for the aerosol forcing in the early period (EP) is used since aerosol emissions data before 1970 were not available.

Abv.	Experiment	Ocean	Radiative forcing
R0	Relaxation run	Relaxation to "present day" (PD, 1994-2011) mean 3D ocean temperature and salinity to diagnose climatological temperature and salinity tendencies	PD greenhouse gases (GHGs) over 1994~2011 and anthropogenic aerosol (AA) emissions over 1994~2010 with AA after 2006 from RCP4.5 scenario (Lamarque et al. 2010, 2011)
C-EP	Early period (EP 1964~1981)	Climatological temperature and salinity tendencies from relaxation run	EP mean GHG and EP mean AA emissions
C-PD	Present Day (PD 1994~2011) with GHG and AA forcings		PD mean GHG and PD mean AA emissions
C-PD-GHG	Present Day (PD 1994~2011) with GHG forcing		PD mean GHG and EP mean AA emissions
C-PD-AA	Present Day (PD 1994~2011) with AA forcing		EP mean GHG and PD mean AA emissions

Table 2. Area averaged decadal changes of three type HW properties over China in observations

	Frequency (events/ year)		**Intensity** (°C)		**Spatial extent** (10^6 km^2)	
	EP	**PD**	**EP**	**PD**	**EP**	**PD**
Compound HWs	0.67	1.85	1.42	3.09	3.66	6.97

928 ## Figure captions

929 **Figure 1.** Time series of area-averaged frequency (units: events/year; left panels), intensity
930 (units: °C; middle panels), and spatial extent (units: 10^6 km^2; right panels) of (a-c) compound, (d-f)
931 daytime, and (g-i) nighttime HWs in extended summer over whole mainland of China (black solid
932 lines), Northeastern China (blue dashed lines), Southeastern China (orange dashed lines), and
933 Western China (green dashed lines). Black dashed lines denote the time means of area-averaged
934 indicators. Red solid lines represent the decadal variations of area-averaged indicators, obtained by
935 9-year running average. The black solid and dashed, as well as the red solid lines are for the left Y-
936 axis, while the dashed blue, orange, and green lines are for the right Y-axis.

937 **Figure 2.** Spatial patterns of differences in frequency (units: events/year; left panels) and intensity
938 (units: °C; right panels) of (a-b) compound, (c-d) daytime, and (e-f) nighttime HWs between the PD
939 and EP. The slashes highlight the regions where the changes are statistically significant at the 90%
940 confidence level based on a two-tailed Student *t*-test. (g) Distributions of 753 stations in China

941 station dataset. The three sub-regional groups are marked with different color dots. The dots in green,
942 orange and purple represent the sub-regions of Northeastern China (NEC), Southeastern China (SEC)
943 and Western China (WC), respectively.

944 **Figure 3.** Climatological means of extended-summer-mean (May–September) Tmax and Tmin
945 during the PD (1994-2011) in observations (a and b) and in the C-PD experiment (c and d). Units
946 are in ℃.

947 **Figure 4.** Spatial patterns of changes in frequency (units: events/year; left panels) and intensity
948 (units: °C; right panels) of compound HWs in response to changes in (a-b) ALL forcing, (c-d) GHG
949 forcing, and (e-f) AA forcing, masked by China boundary. The slashes highlight the regions where
950 the differences are statistically significant at the 90% confidence level based on a two-tailed Student
951 *t*-test.

952 **Figure 5.** Spatial patterns of changes in frequency (units: events/year; left panels) and intensity
953 (units: °C; right panels) of daytime HWs in response to changes in (a-b) ALL forcing, (c-d) GHG
954 forcing, and (e-f) AA forcing, masked by China boundary. The slashes highlight the regions where
955 the differences are statistically significant at the 90% confidence level based on a two-tailed Student
956 *t*-test.

957 **Figure 6.** Spatial patterns of changes in frequency (units: events/year; left panels) and intensity
958 (units: °C; right panels) of nighttime HWs in response to changes in (a-b) ALL forcing, (c-d) GHG
959 forcing, and (e-f) AA forcing, masked by China boundary. The slashes highlight the regions where
960 the differences are statistically significant at the 90% confidence level based on a two-tailed Student
961 *t*-test.

962 **Figure 7.** Area averaged changes in frequency (units: events/year; left panels), intensity (units: °C;

963 middle panels), and spatial extent (units: km^2; right panels) of (a-c) compound, (d-f) daytime, and
964 (g-i) nighttime HWs over whole China, NEC, SEC, and WC in observations and simulations
965 forced by ALL forcing, GHG forcing, and AA forcing. The error bars indicate the 90% confidence
966 intervals based on two-tailed Student *t*-test.

967 **Figure 8.** Spatial patterns of extended-summer-mean response to changes in GHG forcing (C-PD-
968 GHG minus C-EP): (a) surface clear sky downward LW radiation; (b) water vapor (units: kg m^{-2});
969 (c) surface temperature (units: °C); (d) horizontal wind at 850 hPa (units: m s^{-1}); (e) net surface SW
970 radiation; (f) surface SW CRE; (g) total cloud cover (units: %) and (h) relative humidity at 700 hPa
971 (units: %). Radiation with positive value meaning downward and in W m^{-2}. The black dots in a-c
972 and e-h and the blue shadings in d highlight regions where the changes are statistically significant
973 at the 90% confidence level based on a two-tailed Student *t*-test.

974 **Figure 9.** Spatial patterns of extended-summer-mean response to changes in AA forcing (C-PD-AA
975 minus C-EP): (a) total AOD at 0.55 um; (b) net clear sky surface SW radiation; (c) net surface SW
976 radiation; (d) surface SW CRE; (e) total cloud cover (units: %); (f) precipitation (units: mm day^{-1});
977 (g) soil moisture (units: kg m^{-2}) and (h) Tmax (units: °C). Radiation with positive value meaning
978 downward and in W m^{-2}. The black dots highlight regions where the changes are statistically
979 significant at the 90% confidence level based on a two-tailed Student *t*-test.

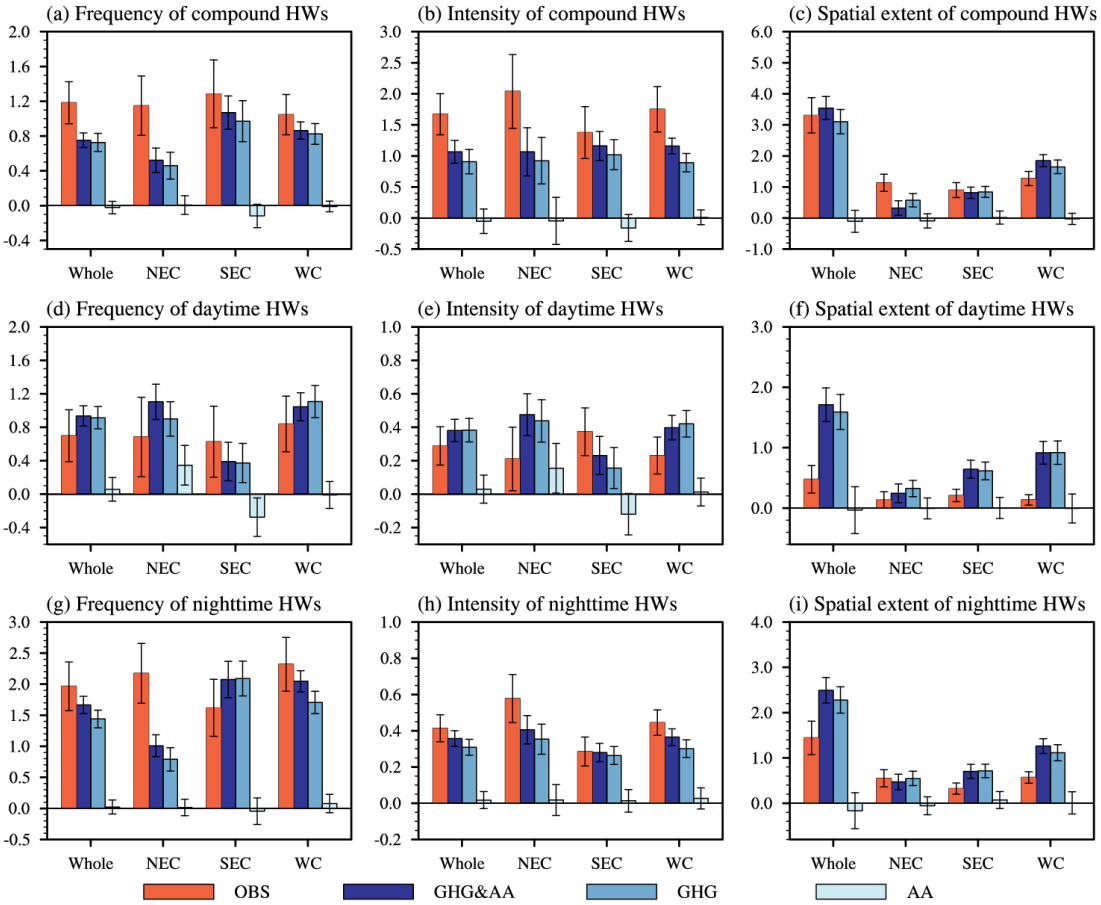

Figure 7. Area averaged changes in frequency (units: events/year; left panels), intensity (units: °C; middle panels), and spatial extent (units: 10^6 km^2; right panels) of (a-c) compound, (d-f) daytime, and (g-i) nighttime HWs over whole China, NEC, SEC, and WC in observations and simulations forced by ALL forcing, GHG forcing, and AA forcing. The error bars indicate the 90% confidence intervals based on two-tailed Student *t*-test.

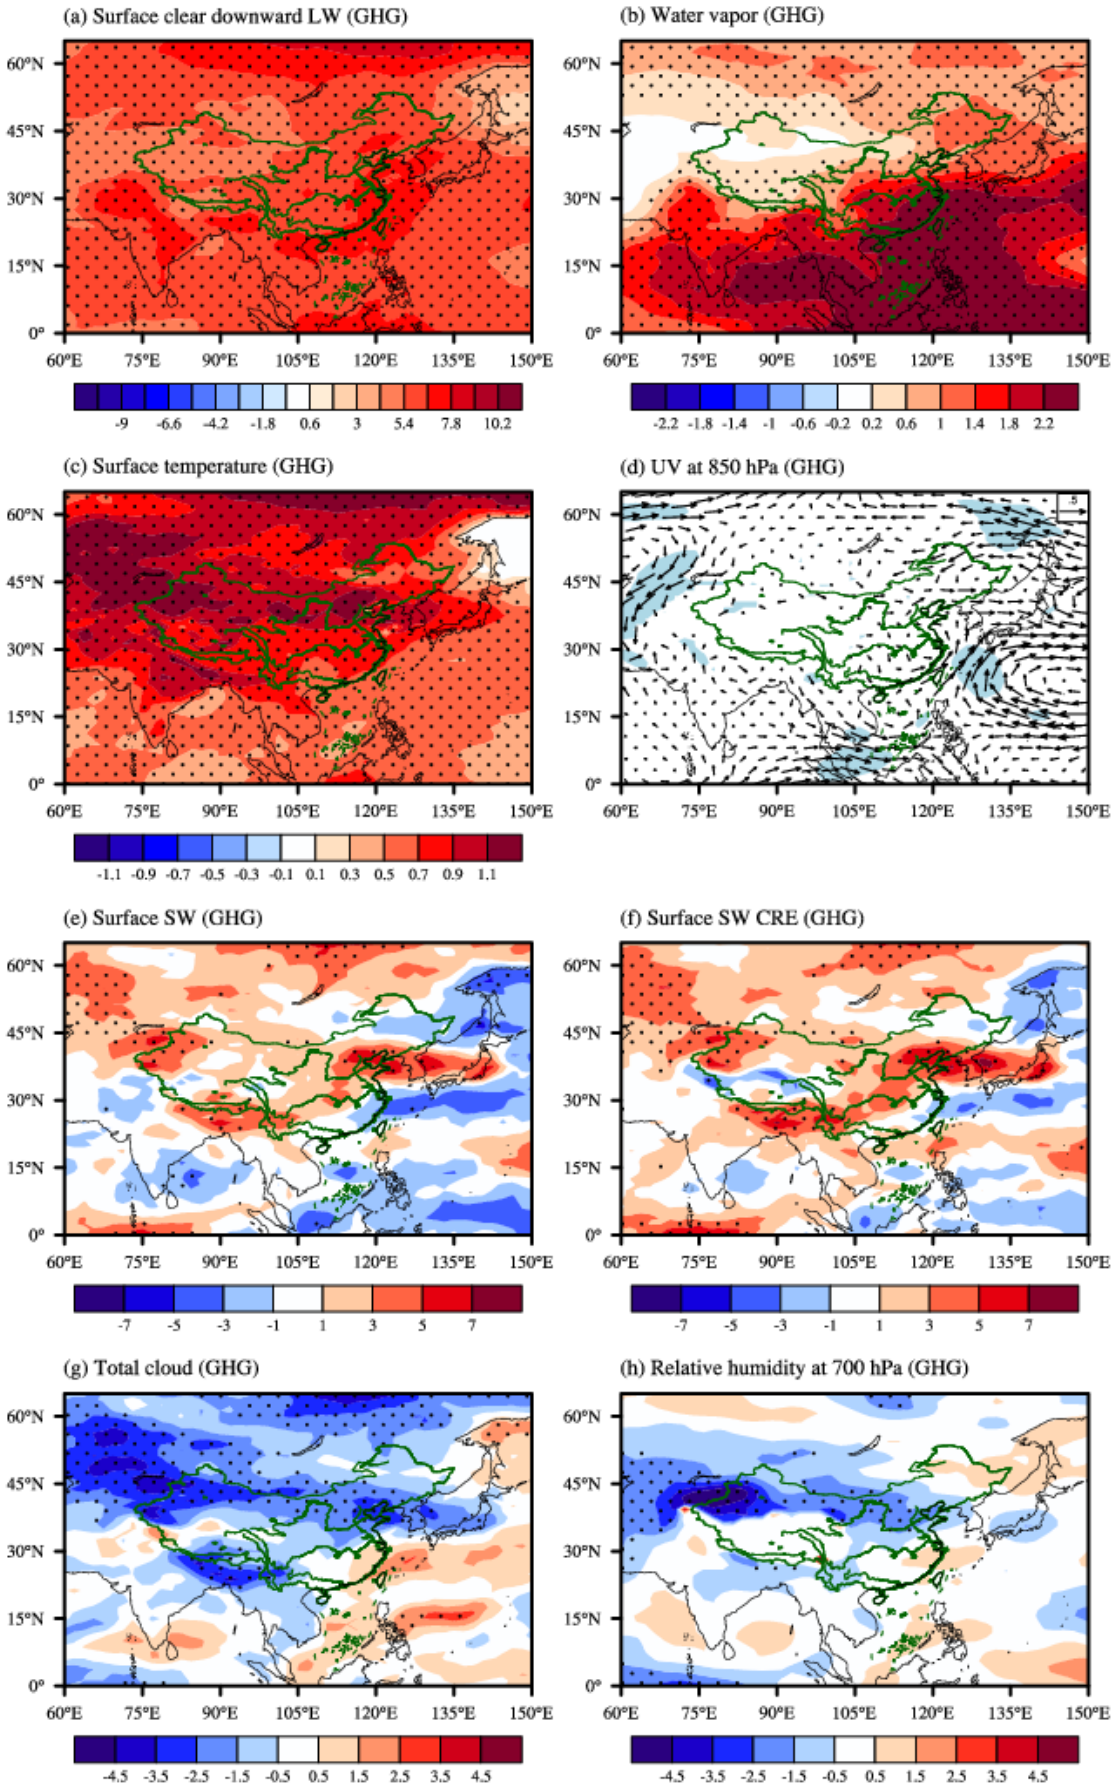

Figure 8. Spatial patterns of extended-summer-mean response to changes in GHG forcing (C-PD-

GHG minus C-EP): (a) surface clear sky downward LW radiation; (b) water vapor (units: kg m^{-2}); (c) surface temperature (units: °C); (d) horizontal wind at 850 hPa (units: m s^{-1}); (e) net surface SW radiation; (f) surface SW CRE; (g) total cloud cover (units: %) and (h) relative humidity at 700 hPa (units: %). Radiation with positive value meaning downward and in W m^{-2}. The black dots in a-c and e-h and the blue shadings in d highlight regions where the changes are statistically significant at the 90% confidence level based on a two-tailed Student *t*-test.

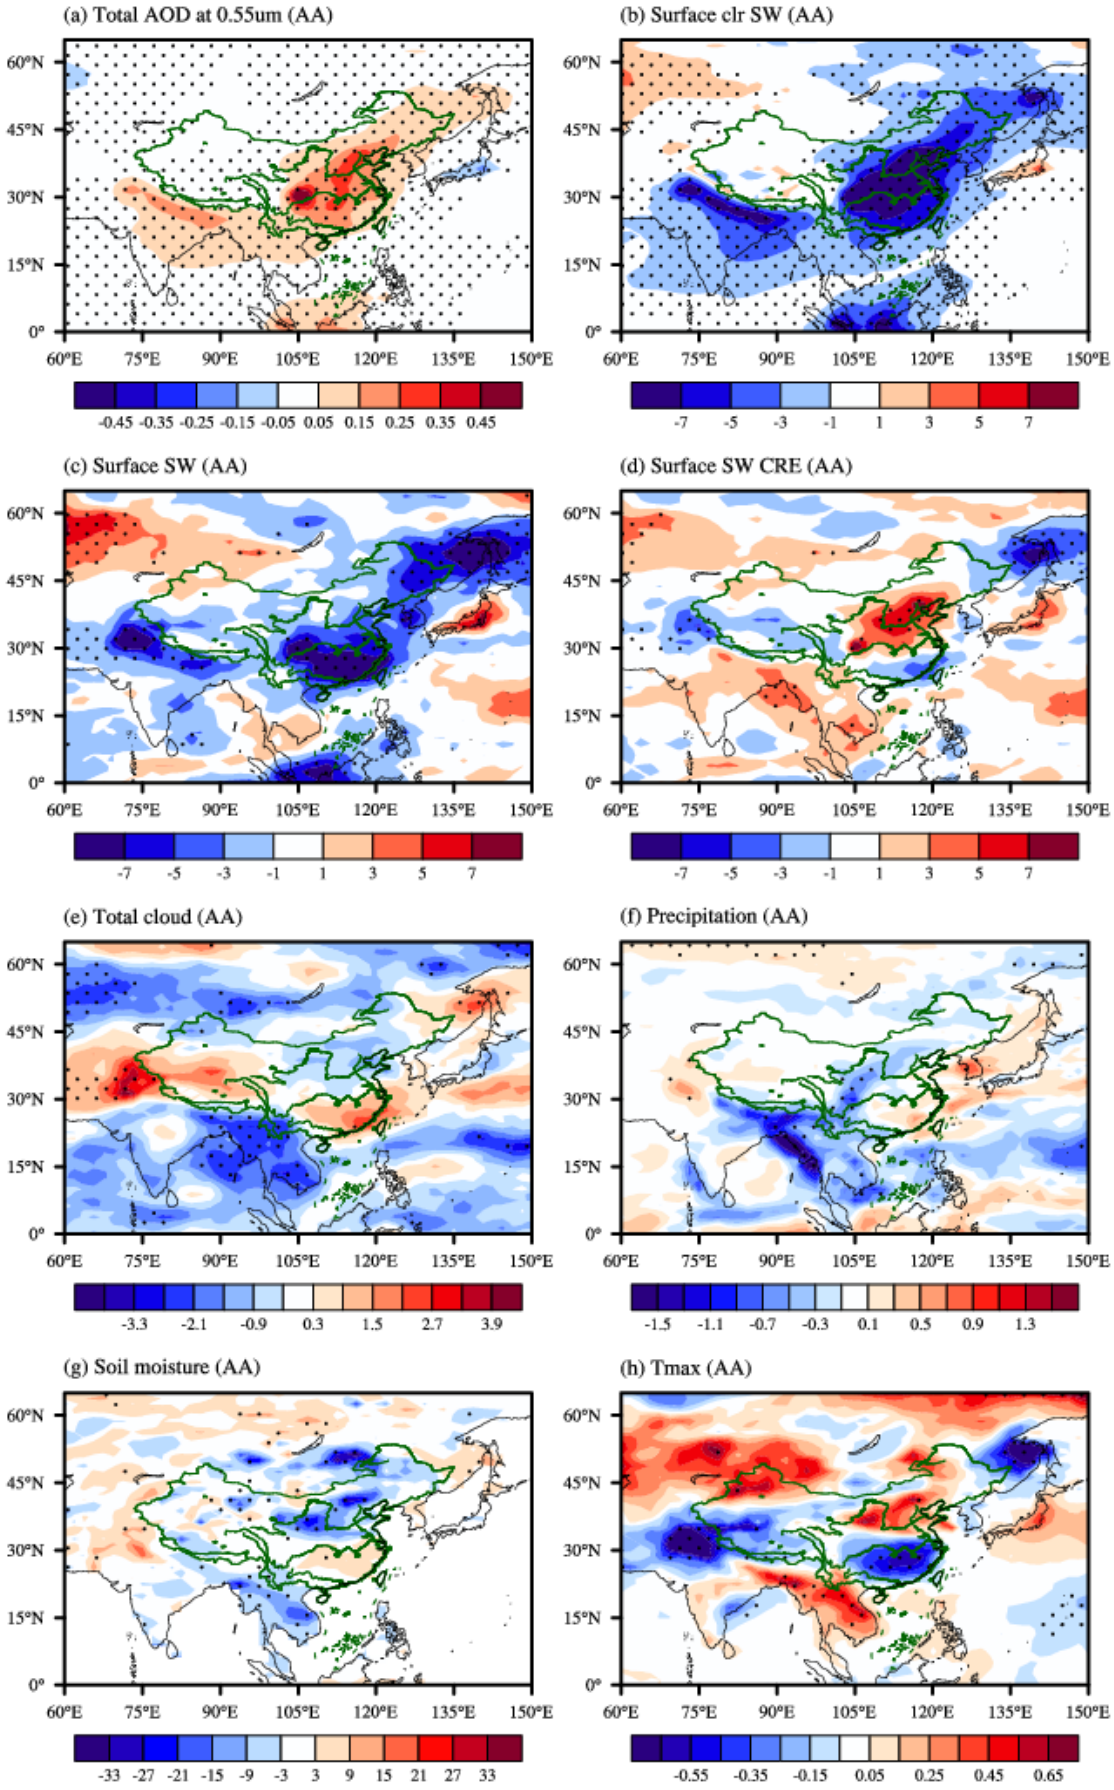

Figure 9. Spatial patterns of extended-summer-mean response to changes in AA forcing (C-

PD-AA minus C-EP): (a) total AOD at 0.55 um; (b) net clear sky surface SW radiation; (c) net surface SW radiation; (d) surface SW CRE; (e) total cloud cover (units: %); (f) precipitation (units: mm day^{-1}); (g) soil moisture (units: kg m^{-2}) and (h) Tmax (units: °C). Radiation with positive value meaning downward and in W m^{-2}. The black dots highlight regions where the changes are statistically significant at the 90% confidence level based on a two-tailed Student *t*-test.
