23

24 People who eat more sugar are less likely to be overweight or obese than people who eat
25 more sugar - at least when we rely on what those people tell us they eat. Alas, for those of
26 us with a sweet tooth, this is no longer true when using an objective measure of intake (1).
27 Unfortunately, this is not restricted to sugar intake, but many other foods: self-reported
28 dietary measures are often biased and neither precise nor accurate. This is well known, and
29 there have been many approaches to improve these measurements: for individual
30 compounds such as sugars however, nutritional biomarkers are among the most reliable
31 instruments (2) as they neither rely on self-reported dietary data nor on food composition
32 tables which introduce further uncertainty.

33 Stable isotope ratios are commonly used in many research areas to investigate diet, but
34 they are remarkably absent from research into human nutrition. O'Brien and colleagues
35 have provided some outstanding data to demonstrate how useful stable isotope ratios can
36 be to nutrition research and made a very good case for a much wider use. They have been
37 used in observational studies (3), but their potential has still not been realised. This is in
38 particular surprising when considering that they can provide information on long-term
39 dietary intake when measured in hair or nails, specimens that are easily accessible (4). A
40 further advantage of stable isotope ratios is that they can provide information about the
41 origin of a compound – for example whether dietary protein has been derived from plant or
42 animal sources.

43 There is currently a considerable interest in the impact of sugar intake on health, especially
44 of added sugar or from sugar sweetened beverages. Research into long-term associations
45 between sugar intake and health are impeded by the difficulties of estimating actual sugar
46 intake accurately. In populations where added sugars are mainly from C4 plants such as
47 corn and sugar cane, stable carbon isotope ratios (CIR, $\delta^{13}\text{C}$) are ideally suitable as

48 biomarkers of added sugar. C3 plants use ribulose-1,5-bisphosphate
49 carboxylase/oxygenase (RuBisCo) for carbon fixation, and this enzyme discriminates
50 against heavier carbon isotopes in CO₂. C4 plants however use a different metabolic
51 strategy which does not result in the same discrimination, and thus C4 plants contain a
52 higher amount of ¹³C and consequently sugar derived from these plants has a higher δ¹³C.
53 Previously, Cook and colleagues have shown that δ¹³C of blood glucose has a strong
54 relationship with sugar intake in a US population (5), where sugar is mainly derived from
55 C4 plants.

56 A key obstacle for the use of nutritional biomarkers is sample collection, processing and
57 analysis. In order to analyse δ¹³C-glucose in blood, extensive sample processing is
58 necessary which is time consuming and laboursome. In this issue of the *Journal of*
59 *Nutrition*, O'Brien and colleagues (6) investigate a very different approach: instead of
60 collecting blood samples with all the associated difficulties, they use breath samples and
61 analyse CIR of exhaled CO₂ using cavity ring-down spectroscopy and found a strong
62 association with added sugar intake. The advantage of the method is that breath can be
63 easily – and non-invasively – sampled and quickly analysed without the need for laborious
64 sample preparation. Like 24h dietary recalls, a breath sample can only provide a dietary
65 snapshot – but with repeat analyses, it can provide useful information on long term diet.

66 The big question is: how can these results be interpreted? In contrast to blood glucose,
67 which is mainly derived from dietary carbohydrates and glucogenic amino acids, exhaled
68 CO₂ can also be derived from fat metabolism. The δ¹³C of lipids is lower than that of non-
69 lipid molecules as lipid synthesis discriminates against the heavier carbon isotope. A shift
70 to carbohydrate metabolism therefore increases δ¹³C-CO₂, independent of the dietary

71 source of carbohydrates (6). A combination with the respiratory quotient could therefore
72 help to interpret the results better.

73 The results of O'Brien and colleagues found the acute change in breath CIR to be
74 strongest, which shows the rapid metabolism of added sugars. The study design did not
75 allow to investigate whether breath CIR could be used to estimate long-term, habitual
76 added sugar and sugar-sweetened beverage consumption, which would make this more
77 useful for long-term dietary assessment. It is important that future research explores this
78 approach and evaluates this biomarker in a larger population.

79 The approach described here has unfortunately one crucial limitation: it relies on a food
80 system where the main sources of added sugar and sugar in SSBs are C4 plants, i.e. corn
81 and sugar cane. While this is the case for the USA, the marker would not work in Europe
82 where sugar is mainly produced from sugar beet, a C3 plant.

83 Using stable isotope ratios to estimate dietary intake in humans is still very much a rough
84 diamond (7), but studies like this help polishing it. There are sufficient data to justify a
85 much wider use in nutritional research, and it is important that such an important technique
86 gets the recognition it deserves. It is time for those working in this field to collaborate
87 more closely with each other and make this technique better known among nutrition
88 researchers and help it realise its potential.
